Acknowledgments

I wish to thank all the people who have contributed to the completion of this work. It gives me great pleasure to mention them here.

First of all, I would like to thank Jacques Carlier and Claude Le Pape, not only for their help and their numerous advices but also for their friendship over the last eight years.

I'm especially grateful to Philippe Chrétienne, Pascal van Hentenryck and Jan–Karel Lenstra who have accepted to review this habilitation thesis.

I'm also indebted to Bernard Dubuisson and Rogelio Lozano, the directors of the CNRS-HeuDiaSyC Laboratory, for their continuous support over the years. Brenda Dietrich, Baruch Schieber and Jonathan Lee deserve special thanks for the great time I'm having at IBM Watson's Mathematical Sciences Department.

I also wish to thank all my colleagues at CNRS, at the University of Technology of Compiègne and at IBM as well as my former colleagues at Bouygues and Ilog who have discussed with me different topics of this habilitation thesis.

I'm also indebted to the many people who have helped in previous work and in preparing this manuscript. I'm especially grateful to Claude Le Pape and Wim Nuijten, the coauthors of our book Constraint-Based Scheduling (Kluwer, 2001). This book is the basis of the second part of this manuscript. Special thanks to the other coauthors of papers that have served as raw material for this manuscript: Jacques Carlier, Jeet Gupta, Antoine Jouglet, Emmanuel Néron, Laurent Péridy, Eric Pinson, Baruch Schieber and Vadim Timkovsky. I also wish to thank Peter Brucker and Sigrid Knust for the many enlightening discussions we have had on scheduling theory.
Baker [9] defines scheduling as the problem of allocating scarce resources to activities over time. In this manuscript, we consider several scheduling problems with a variety of different environments. The two parts of this manuscript provide an overview of two of our major research interests. The first part (Chapters 2 to 5) is dedicated to polynomial time solutions of equal-processing-time scheduling problems. The second one (Chapters 7 to 15) deals with the application of Constraint Programming to scheduling. These two parts reflect the balance we have tried to keep between theoretical and more applied research.

Although all the topics covered in this manuscript are related to scheduling, Parts 1 and 2 are dedicated to very different aspects of scheduling. Some few results discussed in Part 1 are occasionally used in Part 2 but they are independent one from another. In the following, we briefly review the content Parts 1 and 2. More detailed introductions are provided in Sections 1 and 7 respectively.

Scheduling Equal Length Jobs

Looking through the listing of complexity results for scheduling problems [47] one can observe that the vast majority of problems whose complexity status is unknown involve equal-processing-time jobs. Hence, the state-of-the-art in studying the complexity of scheduling problems has reached the level at which approaches and techniques successfully working for equal-processing-time scheduling become especially important. The first part of this manuscript is dedicated to such problems. We have tried to present, within a common framework, our recent results in this area.

- In Chapter 1, after having recalled the Graham, Lawler, Lenstra and Rinnooy Kan Classification Scheme [113], we provide a brief description of equal-processing-time scheduling problems. We discuss the difference between unit and equal-processing-time scheduling problems.

- In Chapter 2, we restrict our study to the single machine case with release dates \( (1|r_i,p_i=p|F) \). We first show that when preemption is allowed and when processing times are equal, we can minimize the weighted number of late jobs in polynomial time. We have a slightly more general result for the non-preemptive case since our dynamic program can handle any “ordered” objective function. Hence we show that \( \sum w_i U_i; \sum w_i C_i \) and \( \sum T_i \), can be minimized in polynomial time.

- In Chapter 3, we consider the situation where \( m \) identical parallel machines are available. In the preemptive case we show that, under the hypothesis that all jobs are released at time 0, the total tardiness problem can be solved in polynomial time thanks to a simple LP formulation of the problem. We also present a dynamic program to minimize the weighted number of late jobs. In the non-preemptive case, we generalize the results obtained on a single machine and we show that, with arbitrary release dates, \( \sum w_i U_i; \sum w_i C_i \) and \( \sum T_i \), can be minimized in polynomial time for any fixed value of \( m \). Finally, we study the weighted number of late jobs

---

1 We have used the following terminology: For theoretical scheduling problems, we have “Jobs” and “Machines”, and we follow the Classification Scheme of Graham, Lawler, Lenstra and Rinnooy Kan [113]. For multiprocessor problems, we follow the widely used “Tasks/Processors” terminology. Finally, to present our Constraint Programming model, we use the “Activity” and “Resource” terms and we will see how they can be used to model many theoretical scheduling problems (e.g., job-shop, Resource-Constrained Project Scheduling, etc.).
Table 1 summarizes the new polynomial time algorithms, for equal-length jobs, that we have obtained in the last few years. As discussed in the introduction of Part 1, a subset only of these algorithms is presented in this manuscript.

- In Chapter 4, we study the situation where a set of $n$ tasks, subjected to release dates, have to be scheduled on $m$ parallel processors. We consider a particular multiprocessor scheduling environment where, for each task $i$, a fixed number $size_i$ of processors is required to execute the task. Yet, the processors required are not specified. We first show that $PM|p_i, size_i, p_i = p|\sum C_i$ can be solved in polynomial time by dynamic programming. Then we study the unit execution time problem ($p_i = 1$) and we show that the minimum maximal tardiness can be computed in polynomial time when $size_i \in \{1, m\}$. In this problem, there are no more than two possible sizes, either 1 (small tasks) or $m$ (tall tasks), and we refer to it as the "tall/small" problem.

- In Chapter 5, we study the situation where $n$ jobs $\{J_1, \ldots, J_n\}$ have to be scheduled on a batching machine. Jobs cannot start before their release dates and all jobs of the same batch start and are completed simultaneously, i.e., at the starting time (respectively at the completion time) of the batch. Several types of batching machines are studied and for each of them, we provide some new complexity results for the case where jobs have identical processing times.

Table 1 summarizes the new polynomial time algorithms, for equal-length jobs, that we have obtained in the last few years. As discussed in the introduction of Part 1, a subset only of these algorithms is presented in this manuscript.

Constraint-Based Scheduling 2

Constraint Programming is a problem-solving paradigm which establishes a neat distinction between, on the one hand, a precise definition of the constraints that define the problem to be solved and, on the other hand, the algorithms and heuristics enabling the selection and cancellation of decisions to solve the problem. The main principles of Constraint Programming are:

- the separation between deductive “constraint propagation” methods, generating additional constraints from existing constraints, and search algorithms, used to systematically explore the solution space [206];
- the “locality principle”, which states that each constraint must propagate as locally as possible, independently of the existence or the non-existence of other constraints [207];
- the distinction between the logical representation of constraints and the control of their use, in accordance with the equation stated by Kowalski for logic programming: Algorithm = Logic + Control [132].

These principles have been widely applied in the area of scheduling, enabling the implementation of flexible and extensible scheduling systems. Indeed, with Constraint Programming all the specific constraints of a given problem can be represented and actually used as a guide toward a solution.

As the number of applications grew, the need emerged to reconcile the flexibility offered by Constraint Programming with the efficiency of specialized Operations Research algorithms. The first step consisted in adapting well-known Operations Research algorithms to the Constraint Programming framework. As a second step, the success of the resulting tools opened a new area of research aimed at the design and implementation of efficient algorithms embeddable in Constraint Programming tools.

In this thesis, we provide a non-exhaustive overview of the most widely used Constraint-Based Scheduling techniques. Following the principles of Constraint Programming, we have three distinct sections:

- Chapter 7 introduces the basic principles of Constraint Programming and provides a model of the constraints that are the most often encountered in scheduling problems.

- Chapters 8, 9, 10 and 11 are focused on the propagation of resource constraints which usually are responsible for the “hardness” of the scheduling problem. In accordance with the locality principle, Chapters 8 and 9 focus on the propagation of one resource constraint considered independently of any other constraint. Chapter 8 deals with a resource of capacity one (which can execute one activity at a time). Chapter 9 considers the more general case in which a resource can execute several activities in parallel. Chapter 10 provides a theoretical comparison of most of the constraint propagation techniques presented earlier. Chapter 11 considers a more recent line of research, allowing to efficiently handle optimization objectives within resource constraints.

- Chapters 12, 13 and 14 are dedicated to the resolution of several academic scheduling problems. These examples illustrate the use and the practical efficiency of the constraint propagation methods of the previous chapters. They also show that besides constraint propagation, the exploration of the search space must be carefully designed, taking into account specific properties of the considered problem (e.g., dominance relations, symmetries, possible use of decomposition rules).

In conclusion, Chapter 15 mentions various extensions of the model and presents promising research directions.

2Most of the material presented in this part comes from Constraint-Based Scheduling (Kluwer, 2001) by Ph. Baptiste, C. Le Pape and W. Nuijten

Part I

Scheduling Equal Length Jobs
Chapter 1

Introduction

Looking through the listing of complexity results for scheduling problems [47] one can observe that the vast majority of problems whose complexity status is unknown involve equal-processing-time jobs. Hence, the state-of-the-art in studying the complexity of scheduling problems has reached the level at which approaches and techniques successfully working for equal-processing-time scheduling become especially important. The first part of this manuscript is dedicated to such problems. We have tried to present, within a common framework, our recent results in this area.

In this introduction we briefly recall (Section 1.1) the Classification Scheme of Graham, Lawler, Lenstra and Rinnooy Kan [113]. We then focus on scheduling problems with identical processing times and we recall some basic results on the special case where processing times equal 1 (Section 1.2). Since many algorithms presented in the following chapters rely on Dynamic Programming, we introduce this technique in Section 1.3. Finally, we provide in Section 1.4 a list of the problems covered in this thesis and we also briefly mention some other results that we have obtained but that are not described in this manuscript.

1.1 Classification Scheme

We use the classification scheme of Graham, Lawler, Lenstra and Rinnooy Kan [113, 38]. It is widely used in scheduling theory and has been extended several times. It allows to represent a large number of scheduling problems under the notation $\alpha|\beta|\gamma$. These parameters describe respectively the machine environment, the job characteristics, and the optimality criterion. Here, we only present the subset of the classification used in this manuscript.

**Machine Environment ($\alpha$)** $\alpha$ consists of 2 parameters $\alpha_1$ and $\alpha_2$.

- $\alpha_1 = 1$ when a single machine is considered.
- $\alpha_1 = P$ when the machines in the problem are identical.
- $\alpha_1 = Q$ when the machines are uniform, *i.e.*, each machine has a speed that linearly affects the processing times.
- $\alpha_1 = R$ when the machines are unrelated, *i.e.*, the processing times on each machine have to be specified.
- More complex machine environments like Flow-Shop ($\alpha_1 = F$), Job-Shop ($\alpha_1 = J$) or Open-Shop ($\alpha_1 = O$) are also considered.

In the shop problems mentioned, the concept of a *job* is used. The term “job” is used when some operations can be rearranged into a strongly related subset. Typically a job is a set of operations linked by a set of precedence constraints. In the shop problems mentioned, each job $J_i$ consists of a set of operations $\{O_{i,1}, \ldots, O_{i,n_i}\}$, and the machine $\mu_{i,j}$ on which each operation $O_{i,j}$ is to be
executed is known in advance. In the Job-Shop Problem, we have chain-like precedence constraints between operations of the same job, i.e., \( O_{i,1} \rightarrow O_{i,2} \rightarrow \ldots \rightarrow O_{i,n_i} \). The Flow-Shop Problem is a special case of the Job-Shop Problem where each job has the same machine ordering for its operations, i.e., \( \forall i,j \mu_{i,j} = j \). In the Open-Shop Problem, there are no precedence constraints but operations of the same job cannot be processed simultaneously.

The second parameter \( \alpha \) denotes the number of machines in the problem. If this parameter is omitted, the number of machines is arbitrary, i.e., it is provided in the data of each instance of the problem. For example, \( \alpha = P5 \) means that there are 5 identical machines while \( \alpha = R \) means that there are an unspecified number of unrelated machines.

**Job Characteristics (\( \beta \))**  As said, the term job is used when some operations can be rearranged into a strongly related subset. Jobs can themselves be related by precedence constraints. The nature of the precedence graph induced by these constraints, if any, is indicated by one of the strings “chain”, “tree”, “prec”, meaning that the precedence graph is a chain, a tree, or any graph.

When jobs are subjected to release dates before which they cannot start, the string “ri” is added to \( \beta \). When jobs are subjected to deadlines before which they must be completed, the string “di” is added. “\( p_i = p \)” and “\( p_i = 1 \)” denote that jobs have identical and unitary processing times, respectively. When preemption is allowed, “pmtn” is added to \( \beta \).

In most of the classical scheduling models, it is assumed that each operation is processed on one machine at a time. However, the relatively recent development of multiprocessor computer systems and of complex manufacturing environments has led researchers to study more complex situations where each operation requires simultaneously several machines (see for instance [35, 88]). We follow the multiprocessor scheduling terminology where “operations” are called “tasks” and “machines” are called “processors”.

- The notation \( size_i \) is used when for each operation \( i \), a fixed number \( size_i \) of processors is required to execute the task (yet, the processors required are not specified).
- The notation \( fix_i \) is used when, for each operation \( i \), the set of processors to be used is known in advance.

We also study some batching problems and we follow Brucker and Knust terminology [47]. In a batching problem, jobs start and are completed simultaneously. On a serial batching machine (“s-batch”), the length of a batch equals the sum of the processing times of its jobs. On a parallel batching machine (“p-batch”), there are at most \( b \) jobs per batch and the length of a batch is the largest processing time of its jobs. These environments are detailed in Chapter 5.

**Optimality Criterion (\( \gamma \))**  In the following, \( C_i \) denotes the completion time of the job \( J_i \). Most of the classical scheduling criteria take into account a due date \( d_i \) that one would like to meet for each job. In contrast to a deadline \( d_i \) which is mandatory, a due date \( d_i \) can be seen as a preference. The tardiness \( T_i \) of \( J_i \) is defined as \( T_i = \max(0, C_i - d_i) \). The notation \( U_i \) is used to denote a unit penalty per late job, i.e., \( U_i \) equals 0 when \( C_i \leq d_i \) and equals 1 otherwise.

Scheduling criteria \( F \) are either formulated as a sum or as a maximum. A weight per job \( w_i \) may be used to give more importance to some jobs. We mention the following well-known optimality criteria:

- Makespan: \( F = C_{\max} = \max C_i \)
- Total weighted flow time: \( F = \sum w_i C_i \)
- Maximum tardiness: \( F = T_{\max} = \max T_i \)
- Total weighted tardiness: \( F = \sum w_i T_i \)
- Total weighted number of late jobs: \( F = \sum w_i U_i \)

See also Figure 1.1 for some scheduling related objective functions.
1.2 Unit vs. Identical Processing Times

When there are no precedence constraints, and when the machines are identical, the problem of scheduling unit-processing time jobs, for any regular function $F$ reduces to a simple flow (or assignment) problem.

In the following we assume that $F = \sum f_i$ is a sum function. Consider an optimal active schedule for $P|p_i = 1|F$. A schedule is said to be active if no job can start earlier without delaying another one or violating its release date. It is easy to see that active schedules are dominant for any regular functions. There are only $O(n)$ relevant time points. This can be seen by considering the two smallest release dates $r$ and $r'$ ($r < r'$). Suppose $x$ jobs have $r$ as release date. If $x \leq r' - r$ then we have at most $x$ relevant time points from $r$ until $r + x$ as it is not useful to schedule any of the $x$ jobs after $r + x$. We can then continue our reasoning with $r'$ and the smallest release date larger than $r'$ ($r''$). If $x > r' - r$ then we have at most $r' - r$ relevant time points between $r$ and $r'$, and we can continue our reasoning with $r'$ and $r''$ and by temporarily assigning a release date $r'$ to $x -(r' - r)$ jobs that have an original release date $r$. By recursively following this reasoning we can see that we will not have more relevant time points than jobs. The cost of scheduling a job $J_i$ at a time point $t_i$ 

\[ (r_i \leq t_i) \] is $f_i(t)$. Moreover, at each time point $t$, less than $m$ jobs can execute. Given the network of Figure 1.2, a maximal flow whose cost is minimal corresponds to an optimal schedule. It can be computed in polynomial time. We refer to [86] for a detailed study of this problem and extensions to uniform parallel machines.

When processing times are equal, the problem cannot, a priori, be reduced to a flow problem. However, if there are no release dates, then on active schedules, start times equal 0 modulo $p$ and so, the problem $P|p_i = p| \sum f_i$ can be reduced to $P|p_i = 1| \sum f'_i$ where $f'_i(t) = f_i(pt)$. Hence, the flow-based approach also applies.

Although the network flow model does not work in general, many problems with identical processing times are still solvable in polynomial time. We have introduced a set of dynamic programming algorithms for this special case.
## 1.3 Dynamic Programming

Dynamic Programming [32] is “an algorithmic technique in which an optimization problem is solved by caching subproblem solutions (memoization) rather than recomputing them” [172]. There are two common characteristics to problems that can be solved by dynamic programming.

- An optimal solution can be decomposed into a set of optimal solutions of sub-problems.
- There are “few” relevant sub-problems to consider; where few means polynomially bounded.

The art of Dynamic Programming lies in the definition of the sub-problems to consider. This can be very easy like in the knapsack problem (given items of different values and volumes, find the most valuable set of items that fit in a knapsack of fixed volume) where each sub-problem is defined by two integer values, the first one identifies the subset of items to consider and the second one is the remaining volume of the knapsack. Unfortunately, sub-problems are not always easy to identify and in most of the cases described in the following chapters, we need some more or less complex dominance rules on optimal schedules to identify them.

## 1.4 Covered Problems

In the following sections, we present a subset of the complexity results that we have recently obtained. Although we study several scheduling environment (single machine, parallel machine, open-shop, etc.), almost all the problems discussed in the following chapters have two common characteristics:

- Jobs have identical processing times,
- machines are identical,
- and there are no precedence constraints.

We have also studied several other theoretical scheduling problems (1|prec, pmtn, \( p_i = p, r_j \sum C_i \), Pm|\( p_i = 1 \), intree|\( \sum C_i \), Q|\( p_i = 1 \), pmtn|\( \sum U_i, P|p_i = 1 \), chains, \( r_i, \max \) [27]; P2|pmtn, outtree, \( r_j, p_j = 1 \)\( \sum C_j \) [26] and 1|s-batch|\( \sum T_i \) [18]) that do not have this three major characteristics. The results obtained on these problems are not reported in this manuscript.

For several of the problems studied in the following sections, we present a solution procedure based on dynamic programming. Such algorithms rely on dominance properties that identify a special job, which, once it is scheduled, allows us to split the problem into two independant sub-problems. The existence of this key job comes from the fact that we can extensively exchange jobs (the absence of precedence constraints and the equal length of jobs play a key role at this point).

Another key observation we use to obtain polynomial-time solutions to non-preemptive problems with equal execution times is that there are very few possible starting times. Indeed, since an optimal non-preemptive schedule is active, i.e., no operation can be shifted to the left without the violation of a constraint, we will see that starting times equal release dates modulo the processing time. In the following, although its definition varies with the exact scheduling environment, \( \Theta \) always denotes the set of all possible starting and completion times.
Chapter 2

Scheduling Equal Length Jobs on a Single Machine

In this Chapter, we restrict our study to the single machine case \((1|r_i,p_i=p|F)\). We first show (Section 2.1) that when preemption is allowed and when processing times are equal, we can minimize the weighted number of late jobs in polynomial time. The corresponding algorithm has been published in [12]. We have a slightly more general result (Section 2.2) for the non-preemptive case since our dynamic program can handle any ordered objective function (see Definition 2). Hence we show that \(\sum w_iU_i, \sum w_iC_i\) and \(\sum T_i\) can be minimized in polynomial time. These results have been published in [13].

2.1 Preemptive Problem, \(1|r_i, pmtn, p_i=p|\sum w_iU_i\)

\(1|pmtn, r_j, \sum w_jU_j\) is NP-hard but can be solved in pseudo-polynomial time by Lawler’s algorithm [142] whose time and space complexities are respectively \(O(nk^2W^2)\) and \(O(k^2W)\), where \(k\) is the number of distinct release dates and where \(W\) is the sum of the weights of the jobs. If weights are equal \(1|pmtn, r_j|\sum U_j\), the problem obviously becomes strongly polynomial; the time and space bounds of Lawler’s algorithm reducing to \(O(n^3k^2)\) and \(O(nk^2)\). So, \(O(n^5)\) and \(O(n^3)\) if all release dates are distinct. In [14], we describe an algorithm for this special case that improves the bounds to respectively \(O(n^4)\) and \(O(n^2)\).

When processing times are equal, the status of the weighted problem was still open. In the following, we describe a dynamic programming from [12] that solves this special case.

2.1.1 Problem Reformulation

Let \(O\) be a subset of jobs and let JPS be the preemptive schedule of these jobs associated to the EDD dispatching rule: whenever the machine is free and one job is available, schedule the job \(J_i\) for which \(d_i\) is the smallest. If a job \(J_j\) becomes available while \(J_i\) is in process, stop \(J_i\) and start \(J_j\) if \(d_j\) is strictly smaller than \(d_i\); otherwise continue \(J_i\). Jackson Preemptive Schedule has several interesting properties (e.g., [55]). In particular, if a job is scheduled on JPS after its due date, there is no preemptive schedule of \(O\) where all jobs are on-time. In the following, \(O\) is said to be feasible if and only if all jobs are on-time in its JPS. Given this definition, searching for a schedule on which the weighted number of late jobs is minimal, reduces to finding a set of jobs whose weight is maximal and whose JPS is feasible.
2.1.2 Dominance Property

**Proposition 1.** For any subset of jobs $Z$, the start and end times of the jobs on the JPS of $Z$ belong to the set $\Theta$.

$$\Theta = \{t | \exists r_i, \exists l \in \{0, \ldots, n\}, t = r_i + lp\}.$$  

*Proof.* We first prove that the end time of a job on the JPS of $Z$ belongs to $\Theta$. Let $J_k$ be any job and let $s$ and $e$ be respectively its start and end times on JPS. Let $t$ be the minimal time point such that between $t$ and $s$ JPS is never idle. Because of the structure of JPS, $t$ is a release date, say $r_x$. The jobs that execute (even partially) between $s$ and $e$ do not execute before $s$ nor after $e$ (because Jackson Preemptive schedule is based upon the EDD rule). Thus $e - s$ is a multiple of $p$. Two cases can occur:

- Either $J_k$ causes an interruption and hence $s = r_k$.
- Or $J_k$ does not cause any interruption and hence the jobs that execute between $r_x$ and $s$, are fully scheduled in this interval. Consequently, $s - t$ is a multiple of $p$.

In both cases, there is a release date $r_y$ (either $r_k$ or $r_x$) such that between $r_y$ and $e$, JPS is never idle and such that $e$ is equal to $r_y$ modulo $p$. On top of that, the distance between $r_y$ and $e$ is not greater than $np$ (because JPS is not idle). Hence, $e \in \Theta$.

Now consider the start time of any job on JPS. This time point is either the release date of the job or is equal to the end time of the 'previous' one. Thus, start times also belong to $\Theta$. $\square$

**Definition 1.** For any time points $t_u, t_v$ in $\Theta$ with $u < v$ and for any integer value $k$ such that $1 \leq k \leq n$,

- let $U_k(t_u, t_v) = \{J_i | i \leq k, r_i \leq t_u \leq t_v\}$
- and for any $m \leq n$, let $W_k(t_u, t_v, m)$ be the maximal weight of a subset $Z \subseteq U_k(t_u, t_v)$ of $m$ jobs such that, the JPS of $Z$ is feasible and ends before $t_v$. If there is no such subset, $W_k(t_u, t_v, m)$ is set to $-\infty$.

In the following, we note $\Theta = \{t_1, t_2, ..., t_q\}$ the ordered set of distinct time-points in $\Theta$. Recall that $q \leq n^2$.

![Preemptive Schedule of $J_k$](image)

**Proposition 2.** For any time points $t_u, t_v \in \Theta$ with $u < v$ and any integer values $k$ and $m$ such that $1 < k \leq n$ and $1 \leq m \leq n$, $W_k(t_u, t_v, m)$ can be computed as follows:

If $r_k \notin [t_u, t_v)$, $W_k(t_u, t_v, m) = W_{k-1}(t_u, t_v, m)$. Otherwise, $W_k(t_u, t_v, m) = \max(W_{k-1}(t_u, t_v, m), W')$ where $W'$ is the maximum of

$$W_{k-1}(t_u, t_x, m_1) + W_{k-1}(t_x, t_y, m_2) + W_{k-1}(t_y, t_v, m_3) + w_k$$
under the constraints
\[
\begin{align*}
t_x, t_y & \in \Theta \\
\max(r_k, t_u) & \leq t_x < t_y \leq \min(d_k, t_v) \\
m_1 + m_2 + m_3 & = m - 1 \\
p(m_2 + 1) & = t_y - t_x
\end{align*}
\]

**Proof.** It is obvious that if \( r_k \notin [t_u, t_v) \), \( W_k(t_u, t_v, m) \) is equal to \( W_{k-1}(t_u, t_v, m) \). In the following, we suppose that \( r_k \in [t_u, t_v) \).

We first prove that \( \max(W_{k-1}(t_u, t_v, m), W') \leq W_k(t_u, t_v, m) \).

- **Case 1:** \( W_{k-1}(t_u, t_v, m) > W' \). Since \( U_{k-1}(t_u, t_v) \subseteq U_k(t_u, t_v) \), we have
  \[
  \max(W_{k-1}(t_u, t_v, m), W') \leq W_k(t_u, t_v, m).
  \]

- **Case 2:** \( W' > W_{k-1}(t_u, t_v, m) \). There exist \( t_x \in \Theta, t_y \in \Theta \) and 3 integers \( m_1, m_2, m_3 \) such that
  \[
  \begin{align*}
  \max(r_k, t_u) & \leq t_x < t_y \leq \min(d_k, t_v) \\
m_1 + m_2 + m_3 & = m - 1 \\
p(m_2 + 1) & = t_y - t_x \\
W' & = W_{k-1}(t_u, t_x, m_1) + W_{k-1}(t_x, t_y, m_2) + W_{k-1}(t_y, t_v, m_3) + w_k
  \end{align*}
  \]

Obviously, the subsets \( U_{k-1}(t_u, t_x) \), \( U_{k-1}(t_x, t_y) \) and \( U_{k-1}(t_y, t_v) \) do not intersect. Thus, the JPS schedules of the subsets that realize \( W_{k-1}(t_u, t_x, m_1), W_{k-1}(t_x, t_y, m_2) \) and \( W_{k-1}(t_y, t_v, m_3) \), put one after another define a valid overall schedule of a set of \( m - 1 \) jobs taken in \( U_{k-1}(t_u, t_v) \). Moreover, between \( t_x \) and \( t_y \) there is enough space to schedule \( J_k \) since \( m_2 \) jobs in \( U_{k-1}(t_x, t_y) \) are scheduled and since \( p(m_2 + 1) = t_y - t_x \) (see Figure 2.1). As a consequence, \( W' \leq W_k(t_u, t_v, m) \).

Now, we prove that \( W_k(t_u, t_v, m) \leq \max(W_{k-1}(t_u, t_v, m), W') \). We only consider the case where \( W_k(t_u, t_v, m) \) is finite otherwise the claim holds. Consider a set \( Z \) that realizes \( W_k(t_u, t_v, m) \). If \( J_k \) does not belong to \( Z \) then \( W_k(t_u, t_v, m) = W_{k-1}(t_u, t_v, m) \leq \max(W_{k-1}(t_u, t_v, m), W') \). Suppose now that \( J_k \in Z \). Let \( t_x \) and \( t_y \) be the start and end times of \( J_k \) on the JPS of \( Z \). Thanks to Proposition 1, we know that \( t_x \in \Theta \) and \( t_y \in \Theta \). We also have \( \max(r_k, t_u) \leq t_x < t_y \leq \min(d_k, t_v) \).

Let \( Z_1, Z_2, Z_3 \) be the partition of \( Z - \{J_k\} \) into the jobs that have a release date between \( t_u \) and \( t_x \), between \( t_x \) and \( t_y \) and between \( t_y \) and \( t_v \). Because of the structure of JPS(\( J_k \) is the job whose due date is maximal), all jobs in \( Z_1 \) are completed before \( t_y \). Moreover, all jobs in \( Z_2 \) start after \( t_x \) and are completed before \( t_y \) and all jobs in \( Z_3 \) are completed before \( t_v \). On top of that, \( p(|Z_2| + 1) = t_y - t_x \) because \( J_k \) is also scheduled between \( t_x \) and \( t_y \). Moreover, we have \(|Z_1| + |Z_2| + |Z_3| + 1 = m|\). Finally the weight of \( Z_1 \) is not greater than \( W_{k-1}(t_u, t_x, |Z_1|) \), the weight of \( Z_2 \) is not greater than \( W_{k-1}(t_x, t_y, |Z_2|) \) and the weight of \( Z_3 \) is not greater than \( W_{k-1}(t_y, t_v, |Z_3|) \). This leads to
\[
W_k(t_u, t_v, m) \leq \max(W_{k-1}(t_u, t_v, m), W').
\]

Our dynamic programming algorithm relies on the above proposition. The values of \( W_k(t_u, t_v, m) \) are stored in a multi-dimensional array of size \( O(n^6) \) (n possible values for \( k \), \( n^2 \) possible values for \( t_u \), \( n^2 \) possible values for \( t_v \), and \( n \) possible values for \( m \)).

- In the initialization phase the value of \( W_1(t_u, t_v, m) \) is set to \( w_1 \) if \( m = 1 \) and if \( p \) is not greater than \( \min(d_1, t_v) - \max(r_1, t_u) \) and to \( -\infty \) otherwise.

- We then iterate from \( k = 2 \) to \( k = n \). Each time, \( W_k \) is computed for all the possible values of the parameters thanks to the formula of Proposition 2 and to the values of \( W_{k-1} \) computed at the previous step.

The maximum weighted number of on-time jobs is equal to
\[
\max(W_n(t_0, t_q, 1), W_n(t_0, t_q, 2), \ldots, W_n(t_0, t_q, n)).
\]

The overall complexity of the algorithm is \( O(n^5) \) for the initialization phase. For each value of \( k \), \( O(n^5) \) values of \( W_k \) have to be computed. For each of them, a maximum among \( O(n^3) \) terms has
2.2 Non-Preemptive Problems, 1|r_i, p_i = p| \sum f_i(C_i)

In this section, we consider the scheduling situation where \( n \) jobs \( J_1, \ldots, J_n \) have to be scheduled on a single machine. Each job is described by a release date \( r_i \), a processing time \( p_i \) and a cost function \( f_i(t) \). This function represents the cost induced by \( J_i \) when it is completed at time \( t \). The problem of minimizing the sum of the \( f_i \) functions consists of finding a set of completion times \( C_i \) for each job \( J_i \) such that (1) jobs start after their release date, \( i.e., \forall i, C_i - p_i \geq r_i \), (2) jobs do not overlap, and (3) the objective function \( \sum_i f_i(C_i) \) is minimal. In the following, a schedule meeting (1) and (2) is said to be feasible.

It is shown in [53, 55, 109] that the problem of minimizing the number of late jobs \( (f_i = U_i) \) is polynomial as soon as processing times are equal, while the general problem is NP-hard [108]. Simons ([201]) describes a polynomial algorithm to minimize the sum of the completion times when processing times are equal. Note that Simon’s algorithm with parallel machines too and that in the single machine case, arbitrary precedence constraints can be taken into account.

These results leave open the status of \( 1|r_i, p_i = p| \sum w_i U_i \), \( 1|r_i, p_i = p| \sum w_i C_i \), \( 1|r_i, p_i = p| \sum T_i \) and \( 1|r_i, p_i = p| \sum w_i T_i \). In the following, we show that single machine problems with identical processing times can be solved polynomially for a large class of so-called ordered objective functions. All these results are extend to parallel machines problems in Chapter 3.

**Definition 2.** \( F \) is an ordered objective function if and only if:

1. \( F \) is a sum function, \( i.e., F = \sum f_i(C_i) \),

2. \( F \) is regular, \( i.e., \forall i, f_i \) is non-decreasing,

3. \( f_i \) is constant after a time point \( \delta_i \), \( i.e., \forall t > \delta_i, f_i(t) = \omega_i \),

4. \( \forall i < j, \delta_i \leq \delta_j \) and \( t \mapsto (f_i - f_j)(t) \) is non-decreasing over \([0, \delta_i]\).

The last condition of the definition ensures that the function has a “Monge”-like property. For such functions, it is known (e.g. [38]) that many unit execution time scheduling problems are polynomially solvable.

It is easy to verify that the weighted number of late jobs, \( \sum w_i U_i \), is an ordered objective function. On the contrary, \( \sum w_i C_i \) and \( \sum T_i \) are not ordered objective functions. However, conditions 1 and 2 of Definition 2 hold for these functions and jobs can be renumbered to meet condition 4.

We show how a function like \( \sum w_i C_i \) or \( \sum T_i \) can be modified, without changing the optimum value, to become an ordered objective function: Consider a large time point \( T \) and alter the functions \( f_i \) after \( T \) so that \( \forall t \geq T, f_i(t) = M \), where \( M \) is another large value. If \( T \) and \( M \) are large enough, the optimum of the modified problem is also the optimum of the original one. Moreover, the modified functions are ordered objective functions.

From now on, we restrict our study to ordered objective functions and we have \( \delta_1 \leq \cdots \leq \delta_n \). By analogy with due date scheduling, we say that a job is late when it is completed after \( \delta_i \) and that it is on-time otherwise. The “late” cost is \( \omega_i \) and the early cost is time-dependant. Notice that a late job can be scheduled arbitrary late.

We first introduce a dominance property (Section 2.2.1) on starting times and we describe the variables of the dynamic programming algorithm and the Theorem that links them together (Section 2.2.2). The dynamic programming algorithm itself is described in Section 2.2.3.
2.2.1 Dominance Property

Proposition 3 provides a characterization of the time points at which jobs start and end on active schedules.

**Proposition 3.** In active schedules, start and completion times belong to

\[ \Theta = \{ t | 3 r_i, \exists t \in \{0, \ldots, n\}, t = r_i + l_p \}. \]

**Proof.** Consider an active schedule and a job \( J_k \). Let \( t \) be the largest time point, before the start time of \( J_k \), at which the machine is idle immediately before \( t \). If \( t \) is not a release date, the job scheduled immediately after \( t \) could be scheduled earlier and thus the schedule would not be active. \( t \) is then a release date, say \( r_1 \). Between \( r_1 \) and the starting time of \( J_k \), \( l \) jobs execute (\( 0 \leq l \leq n-1 \)). Hence the starting time and the ending time of \( J_k \) belong to \( \Theta \). \[\Box\]

Since active schedules are dominant for regular objective functions, we will restrict our search to schedules where starting times belong to \( \Theta \).

2.2.2 Variables Definition and Decomposition Scheme

Recall that late jobs can be scheduled arbitrary late. Hence, there is no point to assign a starting time to late jobs. In the following, when we refer to a schedule \( \mathcal{H} \) of some subset of jobs \( O \), it does not mean that all jobs in \( O \) are in the schedule (the on-time jobs only are in the schedule). So the “cost” of \( \mathcal{H} \) with respect to \( O \) is

- the sum, over all jobs \( J_i \in O \) scheduled in \( \mathcal{H} \), of \( f_i(C_i) \)
- plus the sum, over all other jobs \( J_i \in O \) not scheduled in \( \mathcal{H} \), of \( \omega_i \).

For any integer \( k \leq n \), let \( U_k(s, e) \) be the set of jobs whose index is lower than or equal to \( k \) and whose release date is in the interval \([s, e)\) (same definition as in the preemptive case). Let \( F_k(s, e) \) be the minimal cost over all feasible schedules \( \mathcal{H} \) of the jobs in \( U_k(s - p, e) \) such that

1. no machine is used before \( s \) on \( \mathcal{H} \),
2. no machine is used after \( e \) on \( \mathcal{H} \),
3. starting times of jobs on \( \mathcal{H} \) belong to \( \Theta \).

\( F_k(s, e) \) is always defined since an empty schedule (i.e., a schedule where all jobs of \( U_k(s - p, e) \) are late) is a feasible schedule and meets Constraints 1, 2 and 3. Notice that given our definition, \( F_0(s, e) \) is equal to 0.

![Figure 2.2: Relative positions of \( J_k \) (starting at \( t_k \)), \( s \) and \( e \).](image)

**Proposition 4.** Let \( k \in [1, n] \) and let \([s, e)\) be any time interval. If \( r_k \notin [s - p, e) \), \( F_k(s, e) = F_{k-1}(s, e) \). If \( r_k \in [s - p, e) \), then \( F_k(s, e) \) is equal to \( \min(\omega_k + F_{k-1}(s, e), F') \); where

\[
F' = \min_{\max(s, r_k) \leq t_k} \left\{ F_{k-1}(s, t_k) + F_{k-1}(t_k + p, e) + f_k(t_k + p) \right\} \left\{ t_k + p \leq \min(e, \delta_k) \right\} \left\{ t_k \in \Theta \right\}
\]

(If \( F' \) is undefined, assume that \( F' = \infty \).)
Proof: If \( r_k \notin [s-p, e) \) the proposition holds because \( U_k(s-p, e) = U_{k-1}(s-p, e) \). Now, assume that \( r_k \in [s-p, e) \).

We first prove that \( \omega_k + F_{k-1}(s, e) \geq F_k(s, e) \) and that \( F' \geq F_k(s, e) \).

- The schedule that realizes \( F_{k-1}(s, e) \) and where \( J_k \) is late is feasible for the set of jobs \( U_k(s-p, e) \). The cost of this schedule is \( \omega_k + F_{k-1}(s, e) \). So, we have \( \omega_k + F_{k-1}(s, e) \geq F_k(s, e) \).

- Assume that \( F' \) is finite. According to the definition of \( F' \), there exists a time point \( t_k \) such that (1) \( t_k \geq \max(s, r_k) \), (2) \( t_k \leq \min(e, \delta_k) - p \) and (3) \( F' = F_{k-1}(s, t_k) + F_{k-1}(t_k, e) + f_k(t_k + p) \). Let \( \mathcal{H}_1 \) and \( \mathcal{H}_2 \) be two schedules that realizes respectively \( F_{k-1}(s, t_k) \) and \( F_{k-1}(t_k, e) \). Notice that any job in \( U_{k-1}(s-p, e) \) is either late or scheduled in \( \mathcal{H}_1 \) or in \( \mathcal{H}_2 \). Consider the schedule \( \mathcal{H} \) built as follows: schedule \( J_k \) at time \( t_k \) and “add” \( \mathcal{H}_1 \) and \( \mathcal{H}_2 \). Given the definition of \( F_{k-1} \), \( \mathcal{H} \) is a feasible schedule of \( U_k(s-p, e) \), i.e., jobs do not overlap in time and start (after their release dates) at time points that obviously belong to \( \Theta \). On top of that, \( \mathcal{H} \) is idle before \( s \) and after \( e \). Since \( t_k + p \leq \delta_k \), \( J_k \) is on-time and thus, the cost of \( \mathcal{H} \) is exactly \( F' \). Hence, \( F' \geq F_k(s, e) \).

We now prove that \( \min(\omega_k + F_{k-1}(s, e), F') \leq F_k(s, e) \). Consider a schedule that realizes \( F_k(s, e) \) and let \( O \) be the set of jobs scheduled in this schedule (jobs in \( O - U_k(s-p, e) \) are late). Among all schedules (1) that realize \( F_k(s, e) \) and (2) in which the same set of jobs \( O \) are scheduled, consider the schedule \( \mathcal{H} \) that lexicographically minimizes the vector made of completion times of jobs in \( O \). (The completion time of the job in \( O \), with the smallest index, is minimum, then the completion time of the job in \( O \), with the second smallest index, etc.). The job \( J_k \) is either late or on-time on \( \mathcal{H} \).

- If \( J_k \) is late then \( \mathcal{H} \) is also a feasible schedule for \( U_{k-1}(s-p, e) \) and its cost is exactly \( F_k(s, e) - \omega_k \) (the late cost \( \omega_k \) is removed since \( J_k \) is not considered any longer). Thus, \( F_k(s, e) - \omega_k \geq F_{k-1}(s, e) \) and our claim holds.

- Now assume that \( J_k \) is on-time and let \( t_k \in \Theta \) be the starting time of \( J_k \) in \( \mathcal{H} \). Note that \( t_k + p \leq \min(e, \delta_k) \) and \( \max(s, r_k) \leq t_k \). In the following, we show that this starting time allows us to “partition” all jobs.

Suppose that there is a job \( J_i \) with \( r_i \leq t_k \) that is executed on-time after \( J_k \), at time \( t_i \) in \( \mathcal{H} \) (\( t_k \leq t_i \)). Let \( \mathcal{H}' \) be the schedule obtained from \( \mathcal{H} \) by exchanging the jobs \( J_i \) and \( J_k \). The exchange is valid because \( r_i \leq t_k \) and moreover, both jobs remain on-time because \( \delta_i \leq \delta_k \). The relative cost \( \Delta \) of the exchange is

\[
\Delta = f_i(t_k + p) + f_k(t_i + p) - (f_i(t_i + p) + f_k(t_k + p))
= (f_i - f_k)(t_k + p) - (f_i - f_k)(t_i + p).
\]

Note that \( t_i + p \leq \delta_i \) because \( J_i \) is on-time. Moreover, \( i < k \) and thus \( t \mapsto (f_i - f_k)(t) \) is non-decreasing over \([0, \delta_i]\). Hence \( \Delta \leq 0 \). Given the definition of \( F_k(s, e) \), \( \Delta \) cannot be strictly negative (this would contradict the fact that \( \mathcal{H} \) realizes the minimum). Hence \( \mathcal{H} \) and \( \mathcal{H}' \) have the same cost. However, \( \mathcal{H}' \) is better than \( \mathcal{H} \) for the lexicographical order. This contradicts our hypothesis on \( \mathcal{H} \). Hence, all jobs with a release date lower than or equal to \( t_k \) are late or are scheduled before \( t_k \).

Now, let us decompose \( \mathcal{H} \). Let \( \mathcal{H}_1 \) and \( \mathcal{H}_2 \) denote the left and the right parts of \( \mathcal{H} \) (before \( t_k \) and after \( t_k + p \)). The cost of \( \mathcal{H} \) is the sum of the costs of \( \mathcal{H}_1 \) and \( \mathcal{H}_2 \) plus \( f_k(t_k + p) \). Since all jobs with a release date lower than or equal to \( t_k \) are late or are scheduled before \( t_k \), the cost of \( \mathcal{H}_1 \) is greater than \( F_{k-1}(s, t_k) \) and the cost of \( \mathcal{H}_2 \) is greater than \( F_{k-1}(t_k + p, e) \). Hence, \( F_k(s, e) \geq F_{k-1}(s, t_k) + F_{k-1}(t_k + p, e) + f_k(t_k + p) \).

\[\square\]

2.2.3 A Dynamic Programming Algorithm

Active schedules are dominant so, the optimum is exactly \( F_n(\min_{t \in \Theta} t, \max_{t \in \Theta} t) \). Thanks to Theorem 4, we have a straight dynamic programming algorithm to reach the optimum. The relevant
values for s and e are exactly those in Θ. The values of \( F_k(s, e) \) are stored in a multi-dimensional array of size \( O(n^5) \) (n possible values for k, \( n^2 \) possible values both for s and e). Our algorithm works as follows:

- In the initialization phase, \( F_0(s, e) \) is set to 0 for any values s, e in Θ \((s \leq e)\).

- We then iterate from \( k = 1 \) to \( k = n \). Each time, \( F_k \) is computed for all the possible values of the parameters thanks to the formula of Theorem 4, and to the values of \( F_{k-1} \) computed at the previous step.

The initialization phase runs in \( O(n^4) \) because the size of Θ is upper bounded by \( n^2 \). Afterwards, for each value of k, \( O(n^4) \) values of \( F_k(s, e) \) have to be computed. For each of them, a maximum among \( O(n^2) \) terms is computed (because there are \( O(n^2) \) possible values for \( t_k \in Θ \)). This leads to an overall time complexity of \( O(n^7) \). A rough analysis of the space complexity leads to an \( O(n^5) \) bound but since, at each step of the outer loop on k, one only needs the values of F computed at the previous step \((k - 1)\), the algorithm can be implemented with 2 arrays of \( O(n^4) \) size: one for the current values of F and one for the previous values of F. (To build the optimal schedule, all values of \( F_k(s, e) \) have to be kept; hence the initial \( O(n^5) \) bound applies.)
26 Scheduling Equal Length Jobs on a Single Machine
Chapter 3

Scheduling Equal Length Jobs on Parallel Machines

In this Chapter, we consider the situation where $m$ identical parallel machines are available. In the **preemptive case** (Section 3.1), we show that, if all jobs are released at time 0, the total tardiness problem can be solved in polynomial time thanks to a simple LP formulation of the problem. We also present a dynamic program to minimize the weighted number of late jobs. In the **non-preemptive case** (Section 3.2), we generalize the results obtained on a single machine and we show that $P_{|pmtn|L_{\text{max}}}$, $P_{|w_{ij}|C_{i}}$ and $P_{|w_{i}|U_{i}}$ can be minimized in polynomial time for any fixed value of $m$. These results have been published in [13]. Finally, we study the weighted number of late jobs criteria in a **Unit Execution Time open-shop** environment (Section 3.3). We use a result from Brucker, Jurisch and Jurisch to transform the UET open-shop into a preemptive parallel machine problem and we show that it can be solved in polynomial time with a rather complex Dynamic Program.

### 3.1 Preemptive Problems

#### 3.1.1 Maximal Lateness, $P_{|pmtn|L_{\text{max}}}$

We study the scheduling situation where $n$ jobs $J_1, \ldots, J_n$ with processing times $p_1, \ldots, p_n$ have to be preemptively scheduled on $m$ parallel identical machines. Preemption means that jobs can be interrupted at any time and resumed later on either machine. A Deadline $d_i$ is associated to each job $J_i$ and the question is whether there is a schedule meeting all constraints or not ($P_{|pmtn,d_i|} \rightarrow \Leftarrow$).

**Deadline Scheduling.** Horn [122] has shown that there is a feasible schedule if and only if $\forall i, p_i \leq d_i$ and $\forall i, \sum_j \max(0, p_j - \max(0, d_j - d_i)) \leq md_i$. Sahni’s algorithm builds a schedule [197] in $O(n \log mn)$ steps. Sahni and Cho [198] have shown that the same problem on uniform machines (where each machine execute jobs at its own speed) could be solved in $O(n \log n + mn)$.

**Due-Date Scheduling.** The $L_{\text{max}}$ problem is known to be solvable in $O(n \log m + mn)$ thanks to an Algorithm of Labetouille, Lawler, Lenstra and Rinnoy Kan [136]. Actually this algorithm also works for $Q_{|pmtn|L_{\text{max}}}$ the problem where machines are uniform.

In the following, we describe an $O(n \log n)$ algorithm for $P_{|pmtn|L_{\text{max}}}$. This improves on the previous ones for large values of $m$. To build the optimal schedule, our algorithm works as follows:

1. The optimum $L_{\text{max}}$ value is computed,

2. deadlines are set to the due-dates value plus $L_{\text{max}}$ and the corresponding schedule is built thanks to Sahni’s algorithm

The crucial step is the computation of $L_{\text{max}}$ (Sahni’s algorithm runs in $O(n \log mn)$ steps so, step 2 runs in $O(n \log n)$).
When the maximal lateness $L_{\text{max}}$ is fixed, one can simply increase due-dates of $L_{\text{max}}$ and use the Horn’s [122] conditions to test whether there is a solution with such a maximal lateness. Hence, to reach the minimum maximal lateness, one has to compute the minimal value $L_{\text{max}}$ such that:

$$\forall i, p_i \leq d_i + L_{\text{max}}$$  \hspace{1cm} (3.1)
$$\forall i, \sum_j \max(0, p_j - \max(0, d_j - d_i)) \leq m(d_i + L_{\text{max}})$$  \hspace{1cm} (3.2)

Actually, this minimum value $L_{\text{max}}$ is exactly equal to

$$\max \left( \frac{\sum_j \max(0, p_j - \max(0, d_j - d_i))}{m} - d_i \right)$$  \hspace{1cm} (3.3)

Algorithm 1 computes the values $\sum_j \max(0, p_j - \max(0, d_j - d_i))$ for all $i$ in $O(n \log n)$. We introduce the function $W(t)$

$$W(t) = \sum_j \max(0, p_j - \max(0, \tilde{d}_j - t))$$  \hspace{1cm} (3.4)

Note that the function $W(t)$ is piecewise linear, continuous and non-decreasing. Moreover, the time points at which the slope changes are either deadlines or $\tilde{d}_i - p_i$ values. We first build two ordered lists $\mathcal{D}$ and $\mathcal{DP}$ of integer values that contain respectively the deadlines and the $\tilde{d}_i - p_i$ values. Two indices $i_{\mathcal{D}}$ and $i_{\mathcal{DP}}$ are used to iterate over these lists. $\mathcal{D}$ and $\mathcal{DP}$ are merged in a list $\mathcal{T}$ that contains all relevant time points. The algorithm starts at time 0 and iterate over relevant time points in $\mathcal{T}$.

Between two of them, the slope of the function $W(t)$ does not change and when we encounter a deadline, it is easy to see that the slope decreases of 1 when a $\tilde{d}_i - p_i$ value is encountered and that the slope increases of 1 when a deadline is met (cf., the “while” loops of Algorithm 1 lines 11–14 and 15–18). Once the new slope is computed one has simply to increase $W$ of $\text{slope}(t - t^{\text{old}})$, $t^{\text{old}}$ being the previous value taken by $t$.

**Algorithm 1: Computation of $W(t)$ for $t \in \mathcal{T}$**

1. $\mathcal{D} := \emptyset$, $\mathcal{DP} := \emptyset$
2. for $i = 1$ to $n$
3. \quad Add $\tilde{d}_i$ to $\mathcal{D}$, add $\tilde{d}_i - p_i$ to $\mathcal{DP}$
4. end for
5. Sort $\mathcal{D}$ and $\mathcal{DP}$ in non-decreasing order
6. Merge $\mathcal{D}$ and $\mathcal{DP}$ into $\mathcal{T}$ and remove duplicated values
7. $W := 0$, $t^{\text{old}} := 0$, $\text{slope} := 0$
8. $i_{\mathcal{D}} := 1$, $i_{\mathcal{DP}} := 1$
9. for $t \in \mathcal{T}$
10. \quad $W := W + \text{slope}(t - t^{\text{old}})$ \hspace{0.5cm} at this point, $W(t)$ equals $W$
11. \quad while $\mathcal{DP}[i_{\mathcal{DP}}] = t$
12. \quad \quad $\text{slope} := \text{slope} + 1$
13. \quad \quad $i_{\mathcal{DP}} := i_{\mathcal{DP}} + 1$
14. \quad end while
15. \quad while $\mathcal{D}[i_{\mathcal{D}}] = t$
16. \quad \quad $\text{slope} := \text{slope} - 1$
17. \quad \quad $i_{\mathcal{D}} := i_{\mathcal{D}} + 1$
18. \quad end while
19. \quad $t^{\text{old}} := t$
20. end for

The time complexity of Algorithm 1 is $O(n \log n)$ since (1) the initial sorting requires $O(n \log n)$ steps, (2) merging two lists can be done in linear time and (3) the total number of iterations performed inside the “while” loops equals the size of the lists, i.e., $O(n)$. This algorithm is closely related to the algorithm designed in Section 9.2.3 for computing the “Required Energy Consumption” of a set of jobs over time.
3.1.2 Total Tardiness, $P|p_{\text{mttn}}, p_i = p|\sum T_i$

Brucker, Heitmann and Hurink [40] have shown that preemption is redundant for $P|p_{\text{mttn}}, p_j = 1|\sum T_j$. Hence the problem can be reduced to a simple assignment problem. We introduce a more general technique applicable to a wider range of problems. Let us consider the class of problems

$P|p_{\text{mttn}}, p_i = p|\sum f_j$, where $f_j$ are convex nondecreasing functions such that differences $f_i - f_j$ are all monotone functions. Since tardiness $T_j = \max\{0, C_j - d_j\}$ meet these conditions, $P|p_{\text{mttn}}, p_i = p|\sum T_j$ is in the class. Note that $\sum T_j$ is a piecewise linear function. We assume that the jobs are in a linear order where for each pair of jobs $J_i$ and $J_j$ the functions $f_j - f_i$ are either strictly increasing or constant if $i < j$. As it is shown in [15], such an order always exists.

It can be trivially shown by the exchange argument that for any problem in the class there exists an optimal schedule where $i \leq j \Rightarrow C_i \leq C_j$. Let us consider completion times $C_j$ for all $j = 1, 2, \ldots, n$ as deadlines. It is known [122] that a feasible schedule for the decision problem $P|p_{\text{mttn}}$ with deadlines $C_j$ exits if and only if (see Equation 3.3)

$$\forall j : \sum_{i=1}^n \max\{0, p_i - \max\{0, C_i - C_j\}\} \leq C_j m \text{ and } C_j \geq p_j.$$  

Under the conditions $p_j = p$ and $i \leq j \Rightarrow C_i \leq C_j$ this predicate is

$$\forall j : \sum_{i=j+1}^n \max\{0, p - C_i + C_j\} \leq m C_j - j p \text{ and } C_j \geq p.$$  

Introducing additional variables $X_{ij} = \max\{0, p - C_i + C_j\}$ for all $i = 2, 3, \ldots, n$ and $j = 1, 2, \ldots, n$ we finally obtain the convex program of minimizing $\sum_{j=1}^n f_j(C_j)$ under the linear constraints

$$\forall j : \sum_{i=j+1}^n X_{ij} \leq m C_j - j p \quad \text{and} \quad C_j \geq p,$$

$$\forall i : \forall j : \quad X_{ij} \geq p - C_i + C_j \quad \text{and} \quad X_{ij} \geq 0.$$  

For any convex piecewise linear objective function it can be solved in polynomial time. Once the optimal completion times are known, the optimal schedule can be produced by Sahni’s algorithm [197].

3.1.3 Weighted Number of Late Jobs, $Pm|p_{\text{mttn}}, p_i = p|\sum w_i U_i$

In Section 3.1.3 we propose a variant of Sahni’s Algorithm for $Pm|p_{\text{mttn}}, \tilde{d}_i|\_\_$. The particular structure of the algorithm allows us to derive a pseudopolynomial Algorithm for $Pm|p_{\text{mttn}}|\sum w_i U_i$ (Section 3.1.3). We will see (Section 3.1.3) that when processing times are equal, the Algorithm runs in polynomial time.

An Algorithm to Build a Feasible Schedule

Given a set of deadlines, we describe an algorithm that builds a feasible schedule (if one exists). Informally speaking, the algorithm iterates over jobs and at each step, the current job is scheduled. The first machine is loaded as much as possible, then the second, etc. It is very similar to the algorithm of Sahni [197] but the structure of the schedule is slightly different and will be of prime interest for further developments in this chapter.

For each machine $u$ and each job $J_i$, let $p_i^n$ be the number of time units of $J_i$ scheduled on machine $u$ and let $C_i^n$ denote the completion time of the piece of $J_i$ scheduled on machine $u$. By convention, $C_i^u$ is set to $C_{i-1}^u$ if $J_i$ is not being processed on machine $u$. Throughout one iteration, $p_i^n$ and $C_i^n$ are computed and the processing time as well as the deadline of the job are decreased by $p_i^n$ (cf., Algorithm 2).

It is easy to understand that if the algorithm terminates, all jobs are fully scheduled and the schedule is feasible (decreasing the deadline of $J_i$ at each step ensures that there is no overlap in time of the same job). Notice that structure of the algorithm implies that $C_i^1 \geq C_i^2 \geq \cdots \geq C_i^m$ and that machines are never idle. Such schedules are said to have a “staircase” structure.
Proposition 5. Schedule.

Claim that in $Q$, jobs can be extended if and only if there is a feasible schedule following, is not true, and consider a time point contradict our hypothesis on the starting time of $J$. Hence we have jobs are scheduled one after the other in non-decreasing order of deadlines. This exchange improves the starting time of $J$. Hence there is a job we keep the jobs number of units of minimal.

The sets $S(t) - S_{i-1}(t)$ and $S(t') - S_{i-1}(t')$ are not identical since $J_i$ belongs to the first one and not the second one. Hence there is a job $J_j \in S(t) - S_{i-1}(t)$ that does not belong to $S(t') - S_{i-1}(t')$. We can perform the exchange between $J_i$ and $J_j$ because the deadlines are not lower than $d_i$ (because jobs are scheduled one after the other in non-decreasing order of deadlines). This exchange improves the starting time of $J_i$; which contradicts our hypothesis.

Let $u$ be the smallest index such that $C_{i-1}^{u+1} + p_i \leq d_i$. Algorithm 2 schedules exactly $C_{i-1}^{u} - (d_i - p_i)$ units of $J_i$ between $C_{i-1}^{u+1}$ and $C_{i-1}^{u}$ (after this date, $J_i$ is scheduled continuously until its deadline). Exactly the same amount of $J_i$ is scheduled over this interval in $S$. So over each staircase, the same number of units of $J_i$ are scheduled in both $S$ and $S_{i-1}$. To transform $S$ into an extension of $S_i$, we keep the jobs $J_1, \ldots, J_{i-1}$ fixed, we keep the schedule as it is after time $d_i$ and we reschedule over each time interval defined by a staircase the pieces of jobs that execute there. The rescheduling is achieved thanks to Mc Naughton rule by scheduling first job $J_i$ on the machine whose index is minimal.

Algorithm 2: Scheduling on-time \{$J_1, \ldots, J_n$\}

1: for $u = 1$ to $m$ do
2:     $C_0^u := 0$ initialization with a fake job
3: end for
4: for $i = 1$ to $n$ do
5:     for $u = 1$ to $m$ do
6:         $p_i^u := \max(0, \min(p_i, d_i - C_{i-1}^u))$
7:         Schedule $p_i^u$ units of $J_i$ between $C_{i-1}^u$ and $C_{i-1}^u + p_i^u$ on machine $u$
8:     end for
9: end for
10: if $p_i > 0$ then
11:     All jobs cannot be on-time, exit
12: end if
13: end for

Now, we prove that if the algorithm does not terminate, there is no feasible schedule. In the following, $S_i$ denotes the schedule built by the algorithm at iteration $i$ and for any schedule $S$, $S(t)$ denotes the set of jobs that are being processed at $t$ on $S$. We say that a schedule $Q$ of a subset of jobs can be extended if and only if there is a feasible schedule $S$ of $J_1, \ldots, J_n$ on which all jobs of $Q$ are scheduled at the same time-points as in $S$.

**Proposition 5.** If $S_{i-1}$ can be extended to a feasible schedule, $S_i$ can also be extended to a feasible schedule.

**Proof.** Let $S$ be a schedule that extends $S_{i-1}$ on which the starting time of job $J_i$ is maximal. We claim that in $S$, job $J_i$ is scheduled continuously from its starting time to its deadline. Suppose this is not true, and consider a time point $t < d_i$ such that $J_i$ is not being processed in $[t, t+1)$ but is being processed somewhere before. Let $t' < t$ be the first time slot at which $J_i$ is processed.

If $|S(t)| < m$ then we can obviously remove $J_i$ from $S(t')$ and add it to $S(t)$. This would contradict our hypothesis on the starting time of $J_i$. Hence, $S$ is full at time $t$.

We are going to show that the unit of $J_i$ of $S(t')$ can be exchanged with one unit of some job of $S(t)$. To do that we evaluate $|S(t) - S_{i-1}(t)|$. It is equal to $|S(t)| - |S_{i-1}(t)|$ because $S_{i-1}(t) \subseteq S(t)$. Hence it equals $m - |S_{i-1}(t)|$. Recall that $S_{i-1}$ has a staircase structure so, $|S_{i-1}(t')| \geq |S_{i-1}(t)|$. Hence we have

$$|S(t) - S_{i-1}(t)| \geq m - |S_{i-1}(t')| \geq |S(t') - S_{i-1}(t')|$$

(3.5), (3.6)

The sets $S(t) - S_{i-1}(t)$ and $S(t') - S_{i-1}(t')$ are not identical since $J_i$ belongs to the first one and not the second one. Hence there is a job $J_j \in S(t) - S_{i-1}(t)$ that does not belong to $S(t') - S_{i-1}(t')$. We can perform the exchange between $J_i$ and $J_j$ because the deadlines are not lower than $d_i$ (because jobs are scheduled one after the other in non-decreasing order of deadlines). This exchange improves the starting time of $J_i$; which contradicts our hypothesis.

Let $u$ be the smallest index such that $C_{i-1}^{u+1} + p_i \leq d_i$. Algorithm 2 schedules exactly $C_{i-1}^{u} - (d_i - p_i)$ units of $J_i$ between $C_{i-1}^{u+1}$ and $C_{i-1}^{u}$ (after this date, $J_i$ is scheduled continuously until its deadline). Exactly the same amount of $J_i$ is scheduled over this interval in $S$. So over each staircase, the same number of units of $J_i$ are scheduled in both $S$ and $S_{i-1}$. To transform $S$ into an extension of $S_i$, we keep the jobs $J_1, \ldots, J_{i-1}$ fixed, we keep the schedule as it is after time $d_i$ and we reschedule over each time interval defined by a staircase the pieces of jobs that execute there. The rescheduling is achieved thanks to Mc Naughton rule by scheduling first job $J_i$ on the machine whose index is minimal.

\[\square\]
The time complexity of Algorithm 2 is $O(nm)$. This algorithm is not as efficient as Sahni’s algorithm that can be implemented in $O(n \log mn)$ steps. However, the fact that machine 1 is always loaded as much as possible, then machine 2, etc., is of prime interest for us. This structure of the schedule will be used later on to precompute the set of possible completion times for the $\sum w_i U_i$ problem with identical processing times.

**Recursion Formula for $\sum w_i U_i$**

The main interest of Algorithm 2 is that throughout its execution we have a staircase profile, i.e., machines are never idle and the first machine is always more loaded than the second one, etc. The weighted number of late jobs problem can be solved by dynamic programming. Informally speaking, the current state is defined by an index $i$ that determines the jobs that remain to be scheduled and by the time points $C^1 \geq C^2 \geq \cdots \geq C^m$ at which machines $1, \cdots, m$ become idle. The current job $J_i$ is either late or on-time. In the latter case it is scheduled according to Algorithm 2.

**Definition 3.** For any $C^1 \geq \cdots \geq C^m$ and any $i \leq n$, let $W_i(C^1, \cdots, C^m)$ be the minimum weighted number of late jobs among schedules of $\{J_i, \cdots, J_n\}$ on which machines $1, \cdots, m$ are not available before time $C^1, \cdots, C^m$.

A shown in Proposition 6 We have a simple recursion formula between variables $W_i(C^1, \cdots, C^m)$.

**Proposition 6.** If $C^m + p_i > d_i$ then

$$W_i(C^1, \cdots, C^m) = W_{i+1}(C^1, \cdots, C^m) + w_i$$

otherwise,

$$W_i(C^1, \cdots, C^m) = \min(W_{i+1}(C^1, \cdots, C^m) + w_i, W_{i+1}(C^1, \cdots, C^m))$$

where $C_i^m$ is completion time of $J_i$ when scheduled according to lines 5–11 of Algorithm 2 where $C^1, \cdots, C^m$ play the role of $C_{i-1}, \cdots, C_i - 1^m$.

**Proof.** If $C^m + p_i > d_i$, $J_i$ cannot be on-time and thus, we have to take into account the “late” cost $w_i$ and the remaining jobs are scheduled by induction. If $C^m + p_i \leq d_i$, then $J_i$ can be either late or on-time. If job $J_i$ is on-time, it is valid to schedule it according to Algorithm 2 because it is the unscheduled job with minimum due-date and because we have a staircase profile ($C^1 \geq \cdots \geq C^m$). The remaining jobs are scheduled by induction. If the job $J_i$ is late, we have to again take into account the “late” cost $w_i$. \qed
A Pseudopolynomial Algorithm

Proposition 6 leads to a straight pseudo-polynomial algorithm. First of all, $W_{n+1}(C^1, \cdots, C^m)$ is set to 0 for all possible values of $(C^1, \cdots, C^m)$ such that $\forall j, C_j \leq d_n$ (initialization). Jobs $J_i$ are then taken in decreasing order and the recursion formula is applied on each combination of the $C_i^u$ values with $C^1 \geq \cdots \geq C^m$. This leads to a time complexity of $O(nmD^m)$, where $D = d_n$ is the maximal due-date, since (1) the initialization runs in $O(D^m)$ and (2) for each job $J_i$, there are $O(D^m)$ combination of parameters that have to be tested and each time the cost of scheduling $J_i$ according to Algorithm 2 is $O(m)$. A rough analysis of the space complexity required for this dynamic programming algorithm is $O(nD^m)$. However, at each step of the outer loop on $i$, one only needs the values of $W$ computed at the previous step $(i-1)$, the algorithm can be implemented with 2 arrays of $O(D^m)$ size: one for the current values of $W$ and one for the previous values of $W$.

Identical Processing Times

Now consider the case where jobs have identical processing times. Our idea is to use the Dynamic Programming algorithm of Section 3.1.3 to schedule these jobs. However, we will see that the completion times of jobs take only a small number (i.e., polynomially bounded for any fixed value of $m$) of possible values. Let us come back to the deadline scheduling problem and let us analyze what happens when applying Algorithm 2 on $n$ jobs with identical processing times. Proposition 7 exhibit the structure of the completion time on the first machine while Propositions 8 and 9 provide a recursive formula to compute the structure of the completion times on machine $u$ when it is known on $1, \cdots, u-1$. To simplify presentation, we assume that the first job is a fake job with $p_1 = d_1 = 0$.

Proposition 7. Throughout Algorithm 2, $C_{i}^1$ equals a due-date modulo $p$.

Proof. (By induction on the iteration $i$ of Algorithm 2). If $J_i$ is fully scheduled on machine 1 then $C_{i}^1$ is increased of $p$ and the proposition holds. Otherwise the due-date $d_i$ has been met, i.e., $C_{i}^1 = d_i$ and the proposition also holds. \qed

Proposition 8. If $J_i$ is not completed on machine $u \geq 2$ (i.e., if it is also scheduled on $u+1$, etc.) then $C_{i}^u$, the completion time of $J_i$ on $u$, is equal to $C_{i-1}^{u-1}$.

Proof. Immediately comes from the structure of Algorithm 2 (cf., Figure 3.2). \qed

![Figure 3.2: Illustration of Proposition 8](image-url)

Proposition 9. If $J_i$ is completed on machine $u$ (i.e., if it is not scheduled on $u+1$, etc.) then there is a job $J_j$ that is not completed on machine $u$ such that (cf., Figure 3.3)

$$C_{i}^u = (i-j)p + C_{j}^u - \sum_{v=1}^{u-1} (C_{i}^v - C_{j}^v) \quad (3.9)$$
Proof. Let \( J_j \ (j < i) \) be the job with maximal index that is not completed on machine \( u \) but on a later machine. As shown on Figure 3.3, the \( i - j \) jobs \( \{J_{j+1}, \ldots, J_i\} \) are scheduled between \( C_j^1 \) and \( C_i^1 \) on the first machine, between \( C_j^2 \) and \( C_i^2 \) on the second machine, etc. They are all completed before the \( u \)-th machine. Since machines are never idle and since the total processing time of jobs is \((i - j)p\), we have

\[
\sum_{v=1}^{u} (C_i^v - C_j^v) = (i - j)p \tag{3.10}
\]

Hence, (3.9) holds. Now assume that there is no such job \( J_j \) then all jobs are completed on \( u \) or on a previous machine. So between time 0 and the completion time of \( J_i \) on each machine, we had enough space to schedule all jobs, i.e.,

\[
\sum_{v=1}^{u} C_i^v = ip \tag{3.11}
\]

With the convention \( p_1 = \bar{d}_1 = 0 \), (3.9) holds. \( \square \)

Note that in the previous proposition, \( C_j^u \) is also equal to the completion time of some other job on machine \( u - 1 \) (cf., Proposition 8).

![Figure 3.3: Jobs between \( J_j \) and \( J_i \)](image)

Now let us come back to the \( \sum w_i U_i \) problem and let us compute machine per machine some sets of time points \( T_1, \ldots, T_m \) that include all possible completion times. Due to Proposition 7, we have

\[
T_1 = \{d_i + \lambda p, 1 \leq i \leq n, 1 \leq \lambda \leq n\} \tag{3.12}
\]

Thanks to Proposition 9, we can compute recursively \( T_2, T_3, etc. \). Indeed, a value \( t \in T_u \) is obtained by picking

- \( u - 1 \) values \((\alpha_1, \ldots, \alpha_{u-1})\) respectively in \( T_1, \ldots, T_{u-1} \) (these values play the role of the completion times of \( J_j \) on the \( u - 1 \) first machines in Proposition 9),

- 1 value in \( T_{u-1} \) that corresponds to the completion time of \( J_j \) on the machine \( u \) (as we have noted, this value is also equal to the completion time of some other job on machine \( u - 1 \)),

- \( u - 1 \) values \((\beta_1, \ldots, \beta_{u-1})\) respectively in \( T_1, \ldots, T_{u-1} \) that play the role of the completion times of \( J_i \) on the \( u - 1 \) first machines,

- an integer \( \lambda \in \{1, \cdots, n\} \) that would equal \( j - i \) in Proposition 9
and by computing

\[ t = \alpha + \lambda p - \sum_{v=1}^{u-1} (\beta_v - \alpha_v) \quad (3.13) \]

It is easy to get a rough upper bound of \(|T_u|\):

\[ |T_u| \leq n|T_{u-1}| \prod_{v=1}^{u-1} |T_v|^2 \leq n|T_{u-1}|^{2n-1} \quad (3.14) \]

The key point is that there are \(O(n^{f(m)})\) values in \(T_m\) where \(f\) is some function that depends only of \(m\) (e.g., \(f(m) = 2^m m!\) is a valid upper bound). So, for any fixed value of \(m\), we have a polynomial number of possible completion times. Once they are computed, we can restrict the dynamic programming search to those values of the completion times and we obtain a strongly polynomial algorithm for \(P_m|pmtn, p_i = p| \sum w_i U_i\).

### 3.2 A Non-Preemptive Problem, \(P_m|r_i, p_i = p| \sum w_i U_i\)

In this section, we show that, in the non-preemptive case, most of the results described in Chapter 2 can be extended to the situation where \(m\) parallel identical machines are available.

\(P|r_i| \sum f_i(C_i)\) consists of finding a set of completion times \(C_i\) for each job \(J_i\) such that (1) jobs start after their release date, i.e., \(\forall i, C_i - p_i \geq r_i\), (2) no more than \(m\) machines are used at any time \(t\), i.e., \(\forall t, |\{J_i : C_i - p_i \leq t < C_i\}| \leq m\), and (3) the objective function \(\sum_i f_i(C_i)\) is minimal.

In the following, a schedule meeting (1) and (2) is said to be feasible.

We study the special case where processing times are equal. As shown in the literature, this assumption sometimes allows to exhibit polynomial time algorithms for problems that are NP-hard in the general case:

- Scheduling identical jobs on uniform parallel machines (i.e., on machines that do not run at the same speed), is polynomial when release dates are equal and when the scheduling criteria is non-decreasing in the job completion times (see for instance [86]). In the case of distinct release dates, Dessouky, Lageweg, Lenstra and van de Velde show ([86]) that both the problem of minimizing makespan and the problem of minimizing the sum of the completion times (for a fixed number \(m\) of uniform machines) are polynomial.
- Simons ([201]) provides a polynomial algorithm to minimize the sum of the completion times when processing times are equal \((P|p_i = p, r_i| \sum C_i)\) while the simple problem \((1|r_i| \sum C_i)\) is NP-Hard [147].

We show that, for any ordered objective function \(F\) (Definition 2), \(Pm|r_i, p_i = p|F\) can be solved in polynomial time. Hence, \(Pm|p_j = p, r_j| \sum w_j C_j, Pm|p_j = p, r_j| \sum T_j\) and \(Pm|p_j = p, r_j| \sum T_j\) are in \(P\).

We extend a dominance property (Section 3.2) initially introduced for the single machine case and we describe the variables of the dynamic programming algorithm and the Proposition that links them together (Section 3.2). The dynamic programming algorithm itself is described in Section 3.2.

**Dominance Property**

As for the one-machine case, we can restrict our search to active schedules. Proposition 10 provides a characterization of the time points at which jobs start and end on active schedules.

**Proposition 10.** In active schedules, start and completion times belong to

\[ \Theta = \{t|\exists r_i, \exists l \in \{0, \ldots, n\}, t = r_i + lp\}. \]

**Proof.** Same proof as Proposition 3. \(\square\)
Variables Definition and Decomposition Scheme

Recall that late jobs can be scheduled arbitrary late. Hence, there is no point to assign a starting time to late jobs. In the following, when we refer to a schedule $\mathcal{H}$ of some subset of jobs $O$, it does not mean that all jobs in $O$ are in the schedule (the on-time jobs only are in the schedule). So the “cost” of $\mathcal{H}$ with respect to $O$ is

- the sum, over all jobs $j_i \in O$ scheduled in $\mathcal{H}$, of $f_i(C_i)$
- plus the sum, over all other jobs $j_i \in O$ not scheduled in $\mathcal{H}$, of $\omega_i$.

Roughly speaking, the decomposition scheme for the single machine case (Proposition 4) relies on a particular time point $t_k \in [s, e)$ that allows us to split the problem into two sub-problems (between $s$ and $t_k$ and between $t_k$ and $e$). The same scheme is kept here, however $s$ and $e$ are replaced by two vectors $\sigma$ and $\epsilon$ that represent some resource profiles. We introduce more formally this notion.

**Definition 4.** A resource profile $\xi$ is a vector $(\xi_1, \xi_2, \ldots, \xi_m)$ such that $\xi_1 \leq \xi_2 \leq \ldots \leq \xi_m$ and $\xi_m - \xi_1 \leq p$. In the following, $\Xi$ denotes the set of resource profiles $\xi$ such that $\forall i, \xi_i \in \Theta$.

**Intuitive meaning of resource profiles.** A resource profile $\xi = (\xi_1, \xi_2, \ldots, \xi_m)$ represents the state of the resource at some time point $\xi_1$ (in practice this time point always matches the starting time or the completion time of a job). If $q$ machines are idle at time $\xi_1$ then the $q$ first components of the resource profile equal $\xi_1$. The other components are the completion times of the $m - q$ jobs that are being processed at time $\xi_1$. Since the processing time of jobs is $p$, we have $\forall i, \xi_i - \xi_1 \leq p$.

The state of the resource is considered from a global point of view and thus, the $i^{th}$ component of the resource profile is not systematically related to the $i^{th}$ machine. In the following, some “left” resource profiles $\sigma$ are used to state that no machine is available before $\sigma_1$, one machine is available between $\sigma_1$ and $\sigma_2$; two machines are available between $\sigma_2$ and $\sigma_3$; etc. Conversely, some “right” resource profiles $\epsilon$ are used to state that no machine is available after $\epsilon_m$, one machine is available between $\epsilon_{m-1}$ and $\epsilon_m$; two machines are available between $\epsilon_{m-2}$ and $\epsilon_{m-1}$; etc. The resource profiles $\sigma$ and $\epsilon$ allow us to determine the exact amount of resource that is available at each time point in $[\sigma_1, \epsilon_m]$.

**Definition 5.** Given two resource profiles $\xi$ and $\mu$, $\xi \ll \mu$ if and only if for any index $i$ in $\{1, \ldots, m\}, \xi_i \leq \mu_i$.

Notice that $\ll$ defines a partial order on resource profiles. We introduce a technical proposition that will be used later on.

**Proposition 11.** Given two resource profiles $\xi$ and $\mu$, $\xi \ll \mu$ if and only if for any time point $t$, $|\{i : t < \xi_i\}| + |\{i : \mu_i \leq t\}| \leq m$.

**Proof.** Sufficient condition. (By contradiction.) Let $k$ be the first index such that $\mu_k < \xi_k$. Let us compute $|\{i : t < \xi_i\}| + |\{i : \mu_i \leq t\}|$ for $t = \mu_k$. It is equal to $|\{i : \mu_k < \xi_i\}| + |\{i : \mu_i \leq \mu_k\}|$ which is greater than or equal to $(m - k + 1) + k > m$. This contradicts our hypothesis.

**Necessary condition.** Let $t$ be any time point. In the following, $\delta(P)$ denotes the binary variable that equals 1 if the condition $P$ holds, 0 otherwise. Notice that for any value of $i$, $\delta(t < \xi_i) + \delta(\mu_i \leq t) \leq 1$ because $\xi_i \leq \mu_i$. Hence,

$$|\{i : t < \xi_i\}| + |\{i : \mu_i \leq t\}| = \sum_{i=1}^{m} (\delta(t < \xi_i) + \delta(\mu_i \leq t)) \leq m.$$ 

**□**

We now define the variables of the dynamic programming algorithm. For any integer $k \leq n$, for any resource profiles $\sigma$ and $\epsilon$ ($\sigma \ll \epsilon$), let $F_k(\sigma, \epsilon)$ be the minimal cost over all feasible schedules of the jobs in $U_k(\sigma_m - p, \epsilon_1)$ such that

- starting times belong to $\Theta$,
the number of machines available at time \( t \) to schedule the jobs in the set \( U_k(\sigma_m - p, \epsilon_1) \) is \( m - |\{i : t < \sigma_i\}| - |\{i : \epsilon_i \leq t\}| \).

Notice that given our definition, \( F_0(\sigma, \epsilon) \) is equal to 0.

![Resource profiles](image)

**Proposition 12.** Let \( k \in [1, n] \) and let \( \sigma \ll \epsilon \) be two resource profiles. If \( r_k \notin [\sigma_m - p, \epsilon_1) \), 
\( F_k(\sigma, \epsilon) = F_{k-1}(\sigma, \epsilon) \). If \( r_k \in [\sigma_m - p, \epsilon_1) \), \( F_k(\sigma, \epsilon) \) is equal to \( \min(\omega_k + F_{k-1}(\sigma, \epsilon), F') \); where 

\[
F' = \min_{\theta \in \Xi} \left\{ F_{k-1}(\sigma, \theta) + F_{k-1}(\theta', \epsilon) + f_k(\theta_1 + p) \right\}
\]

\( r_k \leq \theta_1 \)

\( \sigma \ll \theta \)

\( \theta' = (\theta_2, \ldots, \theta_m, \theta_1 + p) \)

\( \theta' \ll \epsilon \)

*(If \( F' \) is undefined, assume that \( F' = \infty \).)*

Notice that in the above formula the value \( \theta' \) is derived from \( \theta \). Figure 3.4 provides an illustration of this proposition. Proposition 12 basically states that the optimum schedule for \( k, \sigma, \epsilon \) can be computed by trying all possible resource profiles \( \theta \) of \( \Xi \) that are “between” the resource profiles \( \sigma \) and \( \epsilon \). For each candidate resource profile \( \theta \), the job \( J_k \) starts at \( \theta_1 \).

**Proof.** First notice that, \( \theta' \) is a resource profile because \( \theta \in \Xi \). Hence the use of \( F_{k-1}(\theta', \epsilon) \) is correct. If \( r_k \notin [\sigma_m - p, \epsilon_1) \) the proposition obviously holds because \( U_k(\sigma_m - p, \epsilon_1) = U_{k-1}(\sigma_m - p, \epsilon_1) \). We now consider the case where \( r_k \in [\sigma_m - p, \epsilon_1) \).

We first prove that \( \omega_k + F_{k-1}(\sigma, \epsilon) \geq F_k(\sigma, \epsilon) \) and that \( F' \geq F_k(\sigma, \epsilon) \). The first claim is obvious (consider the schedule that realizes \( F_{k-1}(\sigma, \epsilon) \), “add” \( J_k \) and put it late). Now, let \( \theta \in \Xi \) be the resource profile that realizes \( F' \). There is a schedule \( \mathcal{H}_1 \) that realizes \( F_{k-1}(\sigma, \theta) \) and a schedule \( \mathcal{H}_2 \) that realizes \( F_{k-1}(\theta', \epsilon) \). Notice that any job in \( U_{k-1}(\sigma_m - p, \epsilon_1) \) is either late or scheduled in \( \mathcal{H}_1 \) or in \( \mathcal{H}_2 \). Consider the schedule \( \mathcal{H} \) build as follows: schedule \( J_k \) at time \( \theta_1 \) and all other jobs in \( U_k(\sigma_m - p, \epsilon_1) \) at the time they were scheduled on \( \mathcal{H}_1 \) or on \( \mathcal{H}_2 \). Let us prove that \( \mathcal{H} \) is a feasible schedule of \( U_k(\sigma_m - p, \epsilon_1) \). Since \( r_k \leq \theta_1 \) and since \( \mathcal{H}_1 \) and \( \mathcal{H}_2 \) are feasible, all jobs are scheduled after their release date. Moreover, we claim that the \( m \)-machine constraint holds.

Let \( t \) be any time point. The number of machines used by the jobs scheduled on \( \mathcal{H}_1 \) is upper bounded by \( m - |\{i : t < \sigma_i\}| - |\{i : \epsilon_i \leq t\}| \). The number of machines used by the jobs scheduled on \( \mathcal{H}_2 \) is upper bounded by \( m - |\{i : t < \theta'_i\}| - |\{i : \epsilon_i \leq t\}| \). Finally, \( J_k \) uses a machine at time \( t \) if and only if \( t \in [\theta_1, \theta_1 + p] \). The resource constraint is satisfied at time \( t \) if the sum of the upper bounds is lower than or equal to \( m - |\{i : t < \sigma_i\}| - |\{i : \epsilon_i \leq t\}| \), i.e., if the following expression is lower than
We have proven that \( H \) is a feasible schedule of \( U_{k-1}(\sigma_m - p, \epsilon_1) \). On top of that, starting times obviously belong to \( \Theta \). The cost of \( H \) is exactly \( F' \) and hence, \( F' \geq F_k(\sigma, \epsilon) \).

**We now prove that** \( \min(\omega_k + F_{k-1}(\sigma, \epsilon), F') \leq F_k(\sigma, \epsilon) \). Consider a schedule that realizes \( F_k(\sigma, \epsilon) \) and let \( O \) be the set of jobs scheduled in this schedule (jobs in \( O - U_k(s - p, \epsilon) \) are late). Among all schedules (1) that realize \( F_k(\sigma, \epsilon) \) and (2) in which the same set of jobs \( O \) are scheduled, consider the schedule \( H \) that lexicographically minimizes the vector made of completion times of jobs in \( O \). (The completion time of the job in \( O \), with the smallest index, is minimum, then the completion time of the job in \( O \), with the second smallest index, etc.). The job \( J_k \) is either late or on-time on \( H \).

If \( J_k \) is late then \( H \) is it is also a schedule of \( U_{k-1}(\sigma_m - p, \epsilon_1) \) that could fit between \( \sigma \) and \( \epsilon \). Its cost is exactly \( F_k(\sigma, \epsilon) - \omega_k \) (the late cost \( \omega_k \) is removed since \( J_k \) is not considered any longer). Hence \( F_{k-1}(\sigma, \epsilon) \leq F_k(\sigma, \epsilon) \).

Now assume that \( J_k \) is on-time and let \( t_k \) be its starting time on \( H \). The proof works as follows.

We first show that on \( H \), jobs with a release date lower than or equal to \( t_k \) are either late or start before or at \( t_k \). We then exhibit a resource profile \( \theta \in \Xi \) such that (1) \( \theta_1 = t_k \), (2) \( \sigma \ll \theta \), (3) \( \theta' = (\theta_2, \ldots, \theta_m, \theta_1 + p) \ll \epsilon \). We then conclude the proof.

In \( H \), jobs \( J_i \) with \( r_i \leq t_k \) are late or start before or at \( t_k \). Suppose that there is an on-time job \( J_i \) with \( r_i \leq t_k \) that is executed at time \( t_i > t_k \) on \( H \). Let \( H' \) be the schedule obtained from \( H \) by exchanging the jobs \( J_i \) and \( J_k \). \( H' \) is better than \( H \) (cf. proof of the second part of Proposition 4). This contradicts our hypothesis on \( H \).

**Definition of \( \theta \).** Let \( \tau \) the vector build component per component as follows: The first component of \( \tau \) is \( t_k \), the time at which \( J_k \) starts. The following components of \( \tau \) are the end times on \( H \) of the jobs (except \( J_k \)) that start before or at \( t_k \) and end strictly after \( t_k \). The following components are the values \( \sigma_t \) that are strictly greater than \( t_k \). Since the resource constraint holds at time \( t \) for \( H \), it is easy to prove that the dimension of \( \tau \) is lower than or equal to \( m \). The vector \( \tau \) is extended to a vector \( \tau' \) of dimension \( m \) by adding a sufficient number of times a component \( t_k \). Let \( \theta \) be the vector obtained from \( \tau' \) by sorting its components in increasing order.

\( \theta \) belongs to \( \Xi \). Consider a component \( \theta_j \) of \( \theta \). Either it is the end time of a job and then \( t_k < \theta_j \leq t_k + p \) or it is a \( \sigma_t > t_k \) value (and then \( t_k < \theta_j \leq t_k + p \) otherwise \( t_k \) would be strictly lower than \( \sigma_t \) and hence no machine would be available at time \( t_k \)) or it is equal to \( t_k \). Hence, all components belong to the interval \([t_k, t_k + p] \), as a consequence \( \theta_m - \theta_1 \leq p \). We have proven that \( \theta \) is a resource profile. It is also easy to verify that all components of \( \theta \) belong to \( \Theta \) and hence \( \theta \in \Xi \). On top of that, it is obvious that \( \theta_1 = t_k \). The proof that \( \sigma \ll \theta \) is also immediate given the definition of \( \theta \).

\( \theta' = (\theta_2, \ldots, \theta_m, \theta_1 + p) \ll \epsilon \). The fact that \( \theta' \) is a resource profile comes immediately from \( \theta \in \Xi \).

Suppose that the relation \( \theta' \ll \epsilon \) does not hold. Then, according to Proposition 11, there is a time point \( t \) such that \( |\{i : t < \theta'_i\}| + |\{i : \epsilon_i \leq t\}| > m \). Recall that \( \epsilon \geq t_k \) otherwise no machine would be available at the time point where \( J_k \) ends. Hence, if \( t < t_k \), \( |\{i : \epsilon_i \leq t\}| = 0 \) and consequently, \( |\{i : t < \theta'_i\}| > m \), which contradicts the fact that \( \theta' \) is a vector of dimension \( m \). As a consequence, we have \( t_k \leq t \). Let \( O \) be the set of jobs that start before or at \( t_k \) and end strictly after \( t_k \). The components of \( \theta' \), are either the completion times of the jobs in \( O \) or the \( \sigma_t \) values that are strictly greater than \( t_k \) or are equal to \( t_k \). Hence, the number of components of \( \theta' \) that are strictly greater than \( t \) is equal to the sum of (1) the number of jobs in \( O \) that end strictly after time \( t \) and of (2) the

\[
m - |\{i : t < \theta'_i\}| - |\{i : \theta_i \leq t\}| + \delta(\theta_1 \leq t < \theta_1 + p)
= m - \sum_{i=1}^{m} \delta(t < \theta'_i) - \sum_{i=1}^{m} \delta(\theta_i \leq t) + \delta(\theta_1 \leq t < \theta_1 + p)
= m - \left( \sum_{i=1}^{m} \delta(t < \theta_i) + \delta(t < \theta_1 + p) \right) - \sum_{i=1}^{m} \delta(\theta_i \leq t) + \delta(\theta_1 \leq t < \theta_1 + p)
= m - \sum_{i=2}^{m} \delta(t < \theta_i) - \delta(t < \theta_1 + p) - \delta(\theta_1 \leq t) + \delta(\theta_1 \leq t < \theta_1 + p)
= 1 - \delta(t < \theta_1 + p) - \delta(\theta_1 \leq t) + \delta(\theta_1 \leq t < \theta_1 + p) \leq 0
\]
number of components of \( \sigma_i \) that are strictly greater than \( t \). Since \( t_k \leq t \), the jobs in \( O \) all start before \( t \). Hence, the total number of jobs \( N_i \) that start before or at \( t \) and end exactly after \( t \) plus the number of components of \( \sigma_i \) that are strictly greater than \( t \), is greater than or equal to \(|\{i : t < \theta_i'\}|\). Hence, \(|\{i : t < \theta_i\}| + |\{i : \varepsilon_i \leq t\}| > m \) leads to, \( N_i + |\{i : t < \sigma_i\}| + |\{i : \varepsilon_i \leq t\}| > m \). This contradicts the fact that the resource constraint is met at time \( t \) on \( \mathcal{H} \).

**Conclusion.** The cost of \( \mathcal{H} \), restricted to the jobs with a release date lower than or equal to \( t_k \) (except \( j_k \)) is not lower than \( F_{k-1}(\sigma, \theta) \). Similarly, the cost of \( \mathcal{H} \) restricted to the jobs with a release date greater \( t_k \) is not lower than \( F_{k-1}(\theta', \epsilon) \). Hence the total cost of \( \mathcal{H} \) \((F_k(\sigma, \epsilon))\), is greater than or equal to \( F_{k-1}(\sigma, \theta) + F_{k-1}(\theta', \epsilon) + f_k(\theta_1 + p) \).

### A Dynamic Programming Algorithm

The optimum is exactly \( F_n(\min_{i \in \Theta} t, \ldots, \min_{i \in \Theta} t) \), \((\max_{i \in \Theta} t, \ldots, \max_{i \in \Theta} t)\). Thanks to Proposition 12, we have a straight dynamic programming algorithm to compute this value. The relevant values for \( \sigma \) and \( \epsilon \) are exactly the vectors in \( \Xi \). We claim that there are \( O(n^2n^{m-1}) = O(n^{m+1}) \) relevant resource profiles. Indeed, there are \( n^2 \) possible values for the first component and once it is fixed there are only \( n \) possible choices for the \( m - 1 \) remaining ones (because of the structure of \( \Theta \) and because the difference between the \( m \)-th component and the first one is upper bounded by \( p \)). This means that there are \( O(n^{2m+2}) \) relevant pairs \((\sigma, \epsilon)\). The values of \( F_k(\sigma, \epsilon) \) are stored in a multi-dimensional array of size \( O(n^{2m+3}) \) \((n \) possible values for \( k \), \( n^{m+1} \) possible values for \( \sigma \) and \( n^{m+1} \) possible values for \( \epsilon \)). Our algorithm then works as follows.

- In the initialization phase, \( F_0(\sigma, \epsilon) \) is set to 0 for any values \( \sigma, \epsilon \) in \( \Xi \) such that \( \sigma \ll \epsilon \).
- We then iterate from \( k = 1 \) to \( k = n \). Each time, \( F_k \) is computed for all the possible values of the parameters thanks to the formula of Proposition 12, and to the values of \( F_{k-1} \) computed at the previous step.

Before analyzing the complexity of the overall algorithm, remark that one can generate easily all possible resource profiles \( \theta \) between \( \sigma \) and \( \epsilon \) \((i.e., \sigma \ll \theta \ll \epsilon)\) in \( O(n^{m+1}) \) steps. Indeed, there are \( O(n^2) \) possible values \( \theta_1 \in \Theta \cap [\sigma_1, \epsilon_1] \). The other components of \( \theta \) belong to \( \Theta \cap [\theta_1, \theta_1 + p] \). There are only \( O(n) \) values in this set. Components \( \theta_i \) are generated, one after another; each time a test verifying that \( \sigma_i \leq \theta_i \leq \epsilon_i \) being performed in constant time.

In the initialization phase, \( O(n^{2m+2}) \) pairs \((\sigma \ll \epsilon)\) are generated. Afterwards, for each value of \( k \), \( O(n^{2m+2}) \) values of \( F_k \) have to be computed. For each of them, \( O(n^{m+1}) \) resource profiles \( \theta \) are generated with \( \sigma \ll \theta \ll \epsilon \). A minimum among \( O(n^{m+1}) \) terms is computed. This leads to an overall time complexity of \( O(n^{3m+4}) \). A rough analysis of the space complexity leads to an \( O(n^{2m+3}) \) bound but since, at each step of the outer loop on \( k \), one only needs the values of \( F \) computed at the previous step \((k - 1) \), the algorithm can be implemented with 2 arrays of \( O(n^{2m+2}) \) size: one for the current values of \( F \) and one for the previous values of \( F \).

Notice that we can perform a backward computation on the values \( F_k(\sigma, \epsilon) \) to recover the optimum schedule. Indeed, for all relevant values of \( k, \sigma \) and \( \epsilon \), it is easy to identify which resource profile \( \theta \) is the best (according to the fundamental recursion formula of Proposition 8). Since the starting time of \( j_k \) is the first component \( \theta_1 \) of \( \theta \), we can recover the starting times of all jobs at once.

### Open Problems

We have shown that scheduling equal length jobs on a fixed number of parallel identical machines is a polynomial problem for some objective functions. We have established that several open scheduling problems such as \( \text{Pm}\{p_{ij} = p, r_j\} \sum_j w_j U_j \), \( \text{Pm}\{p_j = p, r_j\} \sum_j w_j C_j \) or \( \text{Pm}\{p_{ij} = p, r_{ij}\} \sum_j T_j \) are polynomial. The weighted total tardiness problem is still an open problem (even for \( m = 1 \)).

#### 3.3 UET Open-Shops, \( \text{Om}\{p_{ij} = 1, r_i\} \sum w_i U_i \)

We study unit execution time open-shops with integer release dates. As shown below, this problem is strongly related to the problem of scheduling identical jobs on parallel machines. We show that the
minimum weighted number of late jobs can be computed in polynomial time by dynamic programming. The complexity status of the corresponding problem \( Om | p_{ij} = 1, r_i | \sum w_i U_i \) was unknown before.

### 3.3.1 Problem Definition

We have \( n \) jobs \( \{ J_1, \ldots, J_n \} \) to be scheduled on \( m \) machines \( \{ M_1, \ldots, M_m \} \). Each job \( J_i \) consists of \( m \) operations \( \{ O_{i1}, \ldots, O_{im} \} \) that cannot overlap in time. Operation \( O_{ij} \) has to be processed on machine \( M_j \) during \( p_{ij} \) time units. A release date \( r_i \), a due date \( d_i \) and a weight \( w_i \) are associated with each job \( J_i \). In the following, all data are integer. This environment defines an open-shop scheduling problem. We focus on the problem of minimizing, in the non-preemptive case, the weighted number of late jobs; a job \( J_i \) is late if and only if it is completed after its due date \( d_i \).

This problem, denoted as \( O|r_i| \sum w_i U_i \) in the standard scheduling terminology (\( U \) stands for Unit penalty per late job), is NP-hard, even if release dates are equal. We study the special case \( O|r_i, p_{ij} = 1| \sum w_i U_i \) where jobs have Unit Execution Time (UET). In this situation, operations of the same job can be exchanged and the constraint “Operation \( O_{ij} \) has to be processed on machine \( M_j \)” can be replaced by “Operations of the same job have to be processed on distinct machines”.

We refer to [38, 47, 112, 135, 209, 210] for extended and up-to-date complexity results on UET shop scheduling problems.

- Liu and Bulfin have shown that when both release dates and weights are equal, the problem \( O|r_i| \sum U_i \) is polynomial. An \( O(nm^2) \) algorithm is described in [156].
- Brucker, Jurisch, Tautenhahn and Werner have studied the special case where release dates are equal and where the number of machines is fixed \( Om | p_{ij} = 1| \sum w_i U_i \). It is shown in [45] that the problem can be solved in \( O(n^2 m^{m+1}) \), which is \( O(n^2) \) for any fixed value of \( m \).
- Different release dates make the problem harder. Gladky [110] has shown that \( O|r_i, p_{ij} = 1| \sum w_i U_i \) is NP-hard and Kravchenko [133] has extended the NP-hardness proof to \( O|r_i, p_{ij} = 1| U_i \).
- Galambos and Woeginger [107] have shown that for two machines the problem with release dates \( O2|r_i, p_{ij} = 1| \sum w_i U_i \) can be solved in \( O(n^4 \log n) \).

These results leave open the status of the problem \( Om | p_{ij} = 1, r_i | \sum w_i U_i \), for each value of \( m \) greater than or equal to 3. We show that for any fixed value of \( m \), the problem can be solved in \( O(n^{4m^2 - m + 10}) \). In §3.3.2, we recall a well-known transformation of the UET open shop into a preemptive scheduling problem on identical parallel machines. We introduce in §3.3.3 some dominance properties on this problem. In §3.3.4, we define the variables of the dynamic programming algorithm and we present the fundamental recursion formula. The algorithm is described in §3.3.5. Finally, we draw some conclusions in §3.3.6.

### 3.3.2 Transformation

For the sake of completeness, we briefly recall the main result of [43] concerning the transformation of UET open-shops into a identical parallel machine scheduling problem. We refer to [210] for recent developments on the strong links that exist between shop problems and parallel machine scheduling problems. In the following, \( F \) denotes a regular function of the completion times of the jobs.

We can assume that \( m < n \), because when \( n \leq m \), the optimum schedule can be computed as follows: Schedule each operation \( O_{ij} \) at time \( t_{ij} = r_i + j - 1 \) on the machine \( M_{i+1} \) with \( u \equiv i + t_{ij} \mod m \). It is easy to verify that operations of the same job are processed on distinct machines at consecutive (and distinct) time points. Now consider two operations \( O_{ij} \) and \( O_{ij'} \) and suppose that they are processed at the same time (i.e., \( t_{ij} = t_{ij'} \)) on the same machine, then \( i \equiv i' \mod m \). Since \( i \) and \( i' \) are at most equal to \( n \leq m \), we have \( i = i' \) and \( j = j' \), which contradicts our hypothesis. Since each job is completed at its earliest possible completion time, and since \( F \) is regular, the schedule is optimal.
An instance of the UET open-shop problem is transformed into an instance of a preemptive parallel machine problem $Pm|p_{\text{mt}}, p_i = m, r_i|F$ as follows. The number of machines $m$ remains the same, and each job $J_i$ of the open-shop is transformed into a job of the parallel machine problem with the same release date and with a processing time $p_i = m$. We keep the term “operation” for the parallel machine problem. It then denotes a unitary piece of a job. It is obvious that a feasible schedule of the open-shop is also a feasible schedule of the parallel machine problem. Brucker, Jurisch and Jurisch [43] have shown that the converse proposition holds. They introduce an algorithm running in $O(mn \log^2 (mn))$ that allocates a proper machine to each operation.

Since $n$ release dates have to be coded and because $m$ is fixed, the size of the problem is at least $n$ (and does not depend of $m$). Therefore the transformation of Brucker, Jurisch and Jurisch [43] is polynomial in the size of the problem. Hence, UET open-shop problems are polynomial if one can preemptively schedule jobs of length $m$ on $m$ identical parallel machines in polynomial time. Unfortunately the complexity of $Pm|p_{\text{mt}}, p_i = m, r_i|F$ is still unknown, even for simple criteria such as the total completion time or the total number of late jobs. We have described (Chapter 2) an $O(n^{10})$ dynamic programming algorithm for minimizing, in the preemptive case, the weighted number of late jobs (with integer release dates) on a single machine when processing times are equal $1|p_{\text{mt}}, p_i = p, r_i|\sum w_iU_i$. However, it does not seem that this algorithm can be adapted to parallel machines. When preemption is not allowed, the problem of scheduling equal length jobs (with integer release dates) on identical parallel machines is studied and solved in Section 3.2. It is shown that for several criteria $F$, including the weighted sum of the completion times and the sum of the tardiness, the corresponding non-preemptive problem $Pm|p_i = p, r_i|F$ can be solved in $O(p^{4m+4})$. Again, a generalization to the preemptive case of these algorithms, or of other algorithms, initially designed for the non-preemptive scheduling of equal length jobs [53, 55, 86, 109, 201], seems unlikely.

From now on, we consider the parallel machine scheduling problem $Pm|p_{\text{mt}}, p_i = m, r_i|\sum w_iU_i$. This problem is “easier” than the original open-shop because it’s not necessary to precisely allocate machines to operations. In the search for a solution, we only have to check that no more than $m$ operations are scheduled simultaneously. This is the key of the decomposition procedure presented in §3.3.4.

### 3.3.3 Dominance Properties

Since when a job is late it can be arbitrarily late, we look for schedules in which a maximum weighted number of jobs are scheduled between their release date and their due date and we do not schedule the late jobs. So, in the following, jobs that are scheduled at some time point, are early jobs.

From now on, we suppose that jobs are sorted in non-decreasing order of due-dates, i.e., $d_1 \leq d_2 \leq \ldots \leq d_n$. We first define a set of time points $\Theta$ at which jobs start and are completed in some dominant schedules (cf., Proposition 13).

**Definition 6.** $\Theta$ is the set of time points $t$ for which there exists a release date $r_i$ such that $r_i \leq t \leq r_i + n + m$.

Notice that there are at most $n(n + m + 1) = O(n^2)$ values in $\Theta$.

**Proposition 13.** Start times and completion times of operations in active schedules belong to $\Theta$.

**Proof.** A schedule is said to be active if no operation can start earlier without delaying another operation or violating its release date. Let $S$ be such a schedule, let $O_{jk}$ be an operation starting at $t_{jk}$ in $S$ and let $r_i$ be the largest release date earlier than or equal to $t_{jk}$.

If there are at most $m$ time points in $[r_i, t_{jk}]$ where at least a machine is idle then, because at most $m - 1$ operations of $J_j$ are processed in $[r_i, t_{jk}]$, there is a time point $x$ in $[r_i, t_{jk})$ where a machine is idle and where no operation of $J_j$ is processed. Since $r_j \leq r_i$, the first operation of $J_j$ that is processed after $x$ can be shifted to time $x$. This contradicts the fact that $S$ is active.

Hence, between $r_i$ and $t_{jk}$, there are at most $m - 1$ time points where a machine is idle. Since there are at most $mn$ operations to schedule ($n$ jobs of length $m$) and since at most $m$ machines are available to process these operations, the distance between $r_i$ and $t_{jk} - (m - 1)$ is upper bounded by $(mn)/m = n$. Hence, $t_{jk} \leq r_i + n + m - 1$.  \[\square\]
Since for any regular criteria, any schedule can be changed into an active one, Proposition 13 induces a simple dominance criterion: There is an optimal schedule in which starting times and completion times belong to $\Theta$. We refine this dominance property.

**Definition 7.** A schedule is well-ordered in a time interval $[s,e]$ if and only if

- starting times and completion times of operations belong to $\Theta$ and,
- for any operation $O_{ip}$, processed at $t_{ip} \in [s,e]$, at most $(m-1)m+1$ jobs $J_j$, with $r_j \leq t_{ip}$ and $j \leq i$, are completed after time $t_{ip}$.

A schedule is well-ordered if and only if it is well-ordered in any interval.

**Proposition 14.** There is an optimal well-ordered schedule.

**Proof.** Let $O$ be an optimum set of jobs, i.e., a set of early jobs in an optimal schedule and let $S$ be the schedule of the jobs in $O$, that lexicographically minimizes the vector $U$ defined as follows. In (3.15), $t_{ij}$ is the starting time of $O_{ij}$ if $J_i \in O$ and $t_{ij} = 0$ otherwise (late jobs are not considered).

$$U = (t_{11}, \ldots, t_{1m}, t_{21}, \ldots, t_{2m}, \ldots, t_{n1}, \ldots, t_{nm})$$

$U$ is lexicographically minimum, hence, $S$ is active. As a consequence, operations start and are completed at time points in $\Theta$ (cf., Proposition 13). Let $J_i$ be any job in $O$ and let $O_{ip}$ be any operation of this job. Let $V$ be the set of jobs that are processed at time $t_{ip}$ (i.e., one of their operations is processed at time $t_{ip}$). For each job $J_j \in V$, there are at most $m-1$ time points $t$ greater than $t_{ip}$ at which $J_j$ is processed. Hence, there are $(m-1)m$ time points $t$ greater than $t_{ip}$ such that a job processed at $t_{ip}$ is also processed at time $t$. Suppose that more than $(m-1)m$ jobs $J_j \in O$, such that $r_j \leq t_{ip}$ and $j < i$, are completed after time $t_{ip}$. At least one operation of one of these jobs, say $O_{jv}$, is processed after $t_{ip}$ when no job of $V$ is. Let us modify the schedule $S$ by exchanging $O_{ip}$ and $O_{jv}$ (the exchange is possible because $j < i \Rightarrow d_j \leq d_i$). The resulting schedule, after a renumbering of operations, is still optimal. Moreover, the schedule is better for the lexicographical order than $S$; which contradicts our hypothesis on $S$. We have proven that at most $(m-1)m$ jobs $J_j$ with $r_j \leq t_{ip}$ and $j < i$, are completed after time $t_{ip}$. Consequently, at most $(m-1)m+1$ jobs $J_j$ with $r_j \leq t_{ip}$ and $j \leq i$, are completed after time $t_{ip}$. $\square$

3.3.4 Variables Definitions and Fundamental Recursion Formula

We first introduce the remaining processing time (rpt for short) functions that describe the “state” of a schedule at some time point (§3.3.4). They allow us to define the dynamic programming variables (§3.3.4) that are used in the decomposition scheme (§3.3.4 and §3.3.4).

**RPT-Functions**

**Definition 8.** The rpt-function of a schedule $S$ at time $t$ is the function that associates to each job $J_i$ with $r_i < t$, the number of operations of $J_i$ processed after or at $t$.

Of course, for any rpt-function $\tau$ of a schedule at time $t$, we have $0 \leq \tau(J_i) \leq m$ and if $d_i \leq t$ then $\tau(J_i) = 0$ (because late jobs do not appear in the schedule).

**Dynamic Variables**

We consider some sub-problems defined by five parameters $k, s, e, \sigma, \varepsilon$, where $\sigma$ and $\varepsilon$ are some functions respectively defined over $\{J_i, i \leq k, r_i < s\}$ and $\{J_i, i \leq k, r_i < e\}$ that take their values in $[0, m]$. The sub-problem consists of finding a “feasible” (Definition 9) sub-schedule of the $k$-first jobs whose “weight” (Definition 10) in the time-interval $[s,e]$ is maximum.

**Definition 9.** A schedule $S$ of the $k$ first jobs is feasible for $k, s, e, \sigma, \varepsilon$ if and only if (1) it is well-ordered and feasible in $[s,e]$ (at most $m$ operations are processed in parallel) and (2) its rpt-functions at $s$ and $e$ restricted to the $k$ first jobs are $\sigma$ and $\varepsilon$. 
Definition 10. Let $J(S, s, e)$ be the set of the jobs available after or at $s$ ($s \leq r_i$) that are fully processed (i.e., $m$ of their operations are processed) in the interval $[s, e)$ in $S$. The weight of a schedule $S$ in $[s, e)$ is $\sum_{J_i \in J(S, s, e)} w_i$.

Proposition 15 allows us to decompose the computation of the weight of $S$ according to the characteristics of each job. In the following, we use the notation $\delta(P)$ that equals 1 if proposition $P$ holds, and 0 otherwise.

Proposition 15. Let $S$ be a feasible schedule for $k, s, e, \sigma, \varepsilon$, let $t \in [s, e)$, let $\tau'$ be the rpt-function of $S$ at $t + 1$ and let $V$ be the set of jobs that are processed at time $t$. $J(S, s, e)$ is the direct sum of $J(S, t, s, e)$, of $J(S, t + 1, e)$ and of $I$:

$$I = \{ J_i | i \leq k, s \leq r_i < t + 1, \ varepsilon(J_i) = 0, \ \tau'(J_i) + \delta(J_i \in V) > 0 \}$$

(3.16)

Proof. We show that $J(S, s, e) \subseteq J(S, s, t) \cup J(S, t + 1, e) \cup I$. Let $J_i \in J(S, s, e)$. We have $i \leq k$, $s \leq r_i$ and $\varepsilon(J_i) = 0$ (otherwise less than $m$ operations would be processed in $[s, e)$). If $J_i$ is completed before $t$ then $J_i \in J(S, s, t)$. If $J_i$ is such that $t + 1 \leq r_i$ then $J_i \in J(S, t + 1, e)$. Hence, if $J_i$ is completed after or at $t + 1$ and if $r_i < t$ then the rpt-function of $S$ at $t$ is strictly positive. Thus, $\tau'(J_i) + \delta(J_i \in V) > 0$ hence, $J_i \in I$.

It is obvious that $J(S, s, t) \subseteq J(S, s, e)$ and that $J(S, t + 1, e) \subseteq J(S, s, e)$. Now consider a job $J_i \in I$. Since $\tau'(J_i) + \delta(J_i \in V) > 0$, we know that at least one operation of $J_i$ is processed. Hence, the whole job $J_i$ is processed somewhere. Since $\varepsilon(J_i) = 0$ and since $s \leq r_i$, $J_i \in J(S, s, e)$.

Finally, we show that the three sets do not intersect. First, it is obvious that $J(S, s, t) \cap J(S, t + 1, e) = \emptyset$. Second, suppose that there exists a job $J_i \in J(S, s, t) \cap I$. $J_i$ is completed before or at $t$ hence $J_i$ is neither processed at $t$ (i.e., $\delta(J_i \in V) = 0$) nor after $t$ (i.e., $\tau'(J_i) = 0$); which contradicts $\tau'(J_i) + \delta(J_i \in V) > 0$. Third, suppose that $\exists J_i \in J(S, t + 1, e)$ then $t + 1 \leq r_i$ and therefore the job does not belong to $I$. $\blacksquare$

Recall that for each sub-problem we look for a feasible schedule whose weight in $[s, e)$ is maximum. We introduce some variables that represent this maximal weight.

Definition 11. $W_k(s, e, \sigma, \varepsilon)$ is the weight in $[s, e)$ of the heaviest feasible schedules for $k, s, e, \sigma, \varepsilon$.

If there is no such schedule, $W_k(s, e, \sigma, \varepsilon) = +\infty$.

According to Proposition 14, there is an optimal well-ordered schedule. The rpt-function of this schedule after the completion of all jobs is a function $\varepsilon_0$ that equals 0 for each job. The rpt-function of this schedule before or at the minimal release date is defined over $\emptyset$. In the following, $\emptyset$ will denote this function. The maximum weighted number of early jobs is then $W_n(\min(\Theta), \max(\Theta), \emptyset, \varepsilon_0)$.

Informal Description

It now remains to show how the decomposition works. In this section, we describe it in an informal way. A formal presentation is provided in §3.3.4. Let now $k$ be any value in $\{0, \ldots, n\}$ and let $[s, e)$ be any time interval. Let $\sigma$ and $\varepsilon$ be two functions and assume that there is a schedule $S$ with weight $W_k(s, e, \sigma, \varepsilon)$.

- If $J_k$ is not processed in $S$ then, $W_k(s, e, \sigma, \varepsilon) = W_{k-1}(s, e, \sigma, \varepsilon)$.

- If at least one operation of $J_k$ is processed in $[s, e)$, let $t$ be the earliest time where $J_k$ is processed after $s$, let $\tau$ and $\tau'$ be the rpt-functions at time $t$ and $t + 1$ of $S$, finally, let $V$ be the set of jobs that are processed at time $t$ (cf., Figure 3.5). The basic idea is to decompose the problem into a left sub-problem (with $k - 1, s, t, \sigma, \tau$) and a right sub-problem (with $k, t + 1, e, \tau', \varepsilon$). There is a feasible schedule, as heavy as $S$, that can be obtained as follows: Before $t$, follow a schedule that realizes $W_{k-1}(s, t, \sigma, \tau)$, at $t$ process the jobs in $V$ and finally, follow a schedule that realizes $W_k(t + 1, e, \tau', \varepsilon)$ after $t + 1$. The weight of this schedule is then equal to $W_{k-1}(s, t, \sigma, \tau) + W_k(t + 1, e, \tau', \varepsilon)$ plus the weights of “some” jobs that are neither counted in $W_{k-1}(s, t, \sigma, \tau)$ nor in $W_k(t + 1, e, \tau', \varepsilon)$ but that are processed in $[s, e)$. Actually these jobs are those of the set $I$ as defined in Proposition 15.
This decomposition leads to a dynamic programming algorithm where we compute all the possible values of \( W_k(s, e, \sigma, \varepsilon) \) are computed. Operations are processed at time points in \( \Theta \) because feasible schedules are well-ordered. Hence, there are few time points to consider (\(|\Theta| = O(n^2)\)). However there are, \textit{a priori}, \((m + 1)^n\) different rpt-functions for each time point. Fortunately, well-ordered schedules are dominant and allow us to polynomially bound the number of relevant rpt-functions.

**Decomposition**

We define sets of functions that contain all rpt-functions at time \( t \) and \( t + 1 \) of well-ordered schedules in which an operation of \( J_\ell \) is processed at \( t \) (cf., Proposition 16).

**Definition 12.** \( \Psi'_k(t) \) is the set of functions \( \psi : \{J_i|i \leq k, r_i < t\} \rightarrow [0, m] \) such that (1) \( \psi(J_i) > 0 \) for at most \( l \) jobs, (2) \( \psi(J_i) \) either equals 0 or is greater than or equal to \( r_i + m - t \), and (3) \( \psi(J_i) \leq \max(0, d_i - t) \).

**Proposition 16.** Let \( S \) be any feasible schedule for \( k, s, e, \sigma, \varepsilon \) and let \( t \) be any time point at which an operation of \( J_\ell \) is processed. The rpt-functions of \( S \) at \( t \) and \( t + 1 \) respectively belong to \( \Psi'_{m+1}^k(t) \) and to \( \Psi'_{m^2-m+1}^k(t+1) \).

**Proof.** For any rpt-function \( \tau \) at time \( t \) of a schedule, the conditions (2) and (3) of Definition 12 always hold: First, consider any job \( J_i \) such that \( \tau(J_i) > 0 \). Since \( \tau(J_i) > 0 \), the job is early and it cannot be completed before \( r_i + m \). Hence, at most \( r_i + m - t \) operations of \( J_i \) remain to be processed after \( t \). Hence, \( \tau(J_i) \geq r_i + m - t \). Second, notice that for any job \( J_i \), at least \( \max(0, d_i - t) \) operations can be processed after \( t \), and hence, \( \tau(J_i) \leq \max(0, d_i - (t + 1)) \).

Let \( \tau \) and \( \tau' \) be the rpt-functions of \( S \) at time \( t \) and \( t + 1 \). \( S \) is well-ordered in \([s, e]\) and \( J_\ell \) is processed at \( t \) hence, at most \( m^2 - m + 1 \) jobs \( J_j \), with \( r_j \leq t \) and \( j \leq k \), are completed strictly after time \( t \). Thus, \( \tau' \) takes a non-null value for less than \( m^2 - m + 1 \) jobs. Between \( t \) and \( t + 1 \), at most \( m \) operations are processed. Therefore, \( \tau \) takes a non-null value for less than \( m^2 - m + 1 + m = m^2 + 1 \) jobs. \( \square \)

Notice that there are at most \( k! \cdot m! \) functions in each set \( \Psi'_k(t) \) (at most \( l \) jobs have to be picked among \( k \) and a value in \([1, m]\) has to be chosen for each of these jobs). The number of functions in the sets \( \Psi'_{m^2-1}^k(t) \) and \( \Psi'_{m^2-m+1}^k(t+1) \) is therefore polynomially bounded by \( n^{m^2+1} \). This is very important because we will be able to enumerate all relevant rpt-functions at some time point in polynomial time.

From now on, \( k \) denotes any value in \([0, \ldots, n]\), \([s, e]\) is a time interval, \( \sigma \) and \( \varepsilon \) are two rpt-functions. We now introduce the notion of separators. A separator is a set of parameters \( V, \tau' \) related to a time point \( t \in [s, e] \). As shown in Proposition 17, it summarizes the “state” of the schedule at \( t \) jobs in \( V \) are processed at \( t \) and the rpt-function of the schedule at \( t + 1 \) is \( \tau' \).
Let us illustrate the notion of separators on this example.

Definition 13. The triplet \((t, V, \tau')\) is a separator for \(k, s, e, \sigma, \varepsilon\) if and only if

1. \(t\) and \(t + 1\) are time points of \(\Theta\) and \(t \in [\max(s, r_k), \min(e, d_k)]\),
2. \(V \supseteq J_k\) is a subset of at most \(m\) jobs in \(\{J_i| i \leq k, r_i \leq t < d_i\}\),
3. if \(s \leq r_k\), \(\tau'(J_k) = m - 1\) otherwise, \(\tau'(J_k) = \sigma(J_k) - 1\),
4. \(\forall i \leq k\), if \(r_i < s\) then \(\sigma(J_i) \geq \tau'(J_i) + \delta(J_i \in V)\); if \(r_i < t + 1\), \(\tau'(J_i) \geq \varepsilon(J_i)\).

Proposition 17. Let \(S\) be any feasible schedule for \(k, s, e, \sigma, \varepsilon\) and assume that \(t \in [s, e]\) is the first time-point at which an operation of \(J_k\) is processed. Let \(V\) be the set of jobs that are processed at time \(t\) and let \(\tau'\) be the rpt-function of \(S\) at \(t + 1\). The triplet \((t, V, \tau')\) is a separator for \(k, s, e, \sigma, \varepsilon\).

Proof. We first prove that the first and the second conditions of Definition 13 hold. \(t\) and \(t + 1\) are time points of \(\Theta\) because \(S\) is well-ordered in \([s, e]\). On top of that, \(t \in [\max(s, r_k), \min(e, d_k)]\) because operations of \(J_k\) are processed in \([r_k, d_k]\). \(J_k\) obviously belongs to \(V\) and at most \(m\) jobs are processed at \(t\). The jobs \(J_i\) that are processed at \(t\) are such that \(i \leq k\) and \(r_i \leq t < d_i\) (recall that \(S\) is a feasible schedule for \(k, s, e, \sigma, \varepsilon\)).

We now prove that the third condition of Definition 13 holds. If \(r_k \geq s\), then no operation of \(J_k\) is processed before \(s\) and since no operation of \(J_k\) is processed in \([s, t]\) (cf., definition of \(t\)), \(J_k\) is not processed before \(t\). On top of that, \(J_k\) is early because it is processed at \(t\) hence, \(m - 1\) operations remain to be processed after \(t + 1\), i.e., \(\tau'(J_k) = m - 1\). Now assume that \(r_k < s\), then because no operation of \(J_k\) is processed in \([s, t]\), it follows that the number of operations that remain to be processed at \(s\) and at \(t\) are the same, and hence \(\sigma(J_k) = \tau'(J_k) + 1\).

We now prove that the last condition of Definition 13 holds. It holds because the functions \(\sigma(J_i), \tau'(J_i) + \delta(J_i \in V), \tau'(J_i)\) and \(\varepsilon(J_i)\) are the rpt-functions of the same schedule at successive time points \(s \leq t < t + 1 \leq e\).

Proposition 23 introduces a simple relation between the variables \(W\). We need several technical propositions (Propositions 18, 19, 20, 22, 21) to achieve the proof. In the following, we define
Finally, we have to show that equal for time and let not processed before their release dates. Indeed, the constraint holds for the fourth step: (4) if of the rpt-function of have (recall that there is no machine constraint before We claim that of the jobs is processed between at which is the weight of the heaviest schedule among them. Let feasible schedules for is processed strictly after time in is such that is processed strictly after time in is such that is processed at the same time in and that jobs are not processed. The rpt-function of at time is the one of and hence, it is equal to . Similarly, the restrictions to the first jobs of the rpt-function of at time and of are equal. We have to check that these functions are equal for (if they are defined over these jobs). is early and by construction of , operations start and are completed at time points in . We now examine the second condition of the definition of well-ordered schedules. Let be any job and let be any time point in at which one operation of is processed. If , then any job that is processed strictly after in is processed at the same time in . Hence, the constraint holds for because it holds for . If , then remark that (1) any job with is processed strictly after and strictly before is processed at the same time in and (2) that any job with which is processed after is such that ; hence, it is also processed after in . Consequently, the constraint holds for because it holds for and because no operation of is processed in . The case remains. We prove that the constraint holds for (it will consequently hold for all values of ): Since at most of the jobs with are such that . Thus at most of the same jobs are processed after .

**Proposition 18.** If takes a finite value, then there is a feasible schedule for in which is processed between and .

**Proof.** Let be the separator that realizes . and also take finite values; hence, there are two schedules and that realize, respectively, and . We build a schedule as follows: (1) strictly before time , follow ; (2) at time , process jobs in ; (3) strictly after , follow the schedule . This schedule has to be completed because some operations of may have to execute before due to the value of . So we have a fourth step: (4) if , schedule consecutively operations of during during (recall that there is no machine constraint before ). In this last step, we claim that operations are not processed before their release dates. Indeed, is a rpt-function thus, because , we have . We claim that is feasible for . It is obvious that no more than operations are processed at the same time in and that jobs are not processed. The rpt-function of at time is the one of and hence, it is equal to . Similarly, the restrictions to the first jobs of the rpt-function of at time and of are equal. We have to check that these functions are equal for (if they are defined over these jobs). is early and by construction of , operations start and are completed at time points in . We now examine the second condition of the definition of well-ordered schedules. Let be any job and let be any time point in at which one operation of is processed. If , then any job that is processed strictly after in is processed at the same time in . Hence, the constraint holds for because it holds for . If , then remark that (1) any job with is processed strictly after and strictly before is processed at the same time in and (2) that any job with which is processed after is such that ; hence, it is also processed after in . Consequently, the constraint holds for because it holds for and because no operation of is processed in . The case remains. We prove that the constraint holds for (it will consequently hold for all values of ): Since at most of the jobs with are such that . Thus at most of the same jobs are processed after .

**Proposition 19.** Let feasible schedules for in which is processed in exist. Then is the weight of the heaviest schedule among them.

**Proof.** Let be the heaviest schedule in which some operations of are processed in (such a schedule exists because of our hypothesis). Let then be, respectively, the first time-point at which is processed, the set of jobs that are processed at and the rpt-functions of at and
Proposition 20. If \( W_{k-1}(s, e, \sigma, \varepsilon) \) takes a finite value and if either (1) \( r_k < s \) and \( \sigma(J_k) = \varepsilon(J_k) \) or (2) \( s \leq r_k < e \) and \( \varepsilon(J_k) = 0 \) or (3) \( s \leq r_k < e \) and \( \varepsilon(J_k) = m \) or (4) \( e \leq r_k \) then there is a feasible schedule for \( k, s, e, \sigma \) where \( J_k \) is not processed in \( [s, e) \).

Proof. Let \( \mathcal{S} \) be a schedule that realizes \( W_{k-1}(s, e, \sigma, \varepsilon) \). We modify the schedule \( \mathcal{S} \) by adding eventually some operations before \( s \) and after \( e \). Since an unlimited number of operations can be processed in parallel before \( s \) and after \( e \), such additions are valid. The proof follows the cases introduced in Proposition 20:

1. \( r_k < s \) and \( \sigma(J_k) = \varepsilon(J_k) \). First notice that if \( \sigma(J_k) = 0 \) then \( \mathcal{S} \) is feasible for \( k, s, e, \sigma, \varepsilon \). If \( \sigma(J_k) > 0 \) then, because \( \sigma \) is a rpt-function, we know that \( \sigma(J_k) \geq r_k + m - s \). Hence, we can schedule \( m - \sigma(J_k) \) operations before \( s \). Similarly, we can schedule \( \varepsilon(J_k) \) operations after \( e \). The overall schedule is then feasible for \( k, s, e, \sigma, \varepsilon \).

2. \( s \leq r_k < e \) and \( \varepsilon(J_k) = 0 \). \( \mathcal{S} \) is feasible for \( k, s, e, \sigma, \varepsilon \) (\( J_k \) is late in this schedule)

3. \( s \leq r_k < e \) and \( \varepsilon(J_k) = m \). \( m \) operations are added after \( e \) (this is possible because \( \varepsilon(J_k) \leq \max(0, d_k - t) \) leads to \( m \leq d_k - t \)). The overall schedule is then feasible for \( k, s, e, \sigma, \varepsilon \).

4. \( e \leq r_k \). \( \mathcal{S} \) is feasible for \( k, s, e, \sigma, \varepsilon \).

\[ \sum_{J_i \in J(s, s, e)} w_i \leq W' \] (3.19)
Proposition 22. Let feasible schedules for \( k, s, e, \sigma \) where \( J_k \) is not processed in \([s, e]\) exist. Then \( W_{k-1}(s, e, \sigma, \varepsilon) \) is the weight of the heaviest among them.

Proof. Let \( S \) be any feasible schedule for \( k, s, e, \sigma \) in which \( J_k \) is not processed in \([s, e]\) and whose weight \( \sum_{i \in J(S, s, e)} w_i \) is maximal. The weight of \( J_k \) is not taken into account (cf. definition of \( J(S, s, e) \)). Hence, \( \sum_{i \in J(S, s, e)} w_i \) equals the weight of the same schedule in which \( J_k \) has been removed. This weight is lower than or equal to \( W_{k-1}(s, e, \sigma, \varepsilon) \). Hence, there exists a schedule that realizes \( W_{k-1}(s, e, \sigma, \varepsilon) \). We could add some operations of \( J_k \) before \( s \) and after \( e \) to transform this schedule into a feasible schedule for \( k, s, e, \sigma, \varepsilon \) (similar as in the proof of Proposition 20). Therefore, we could prove that \( W_{k-1}(s, e, \sigma, \varepsilon) \) is the weight of a schedule in which \( J_k \) is not processed in \([s, e]\).

Proposition 23. If either (1) \( r_k < s \) and \( \sigma(J_k) = \varepsilon(J_k) \) or (2) \( s \leq r_k < e \) and \( \varepsilon(J_k) = 0 \) or (3) \( s \leq r_k < e \) and \( \varepsilon(J_k) = m \), or (4) \( e \leq r_k \), then \( W_k(s, e, \sigma, \varepsilon) = \max(W', W_{k-1}(s, e, \sigma, \varepsilon)) \). If none of the four conditions holds, \( W_k(s, e, \sigma, \varepsilon) \) equals \( W' \).

Proof. We first prove that, \( W_k(s, e, \sigma, \varepsilon) \geq W' \). This is obvious if \( W' \) does not take a finite value. Now assume that it does. Hence, there is a feasible schedule for \( k, s, e, \sigma \) in which \( J_k \) is processed in \([s, e]\) (Proposition 18) and \( W' \) is the weight of the heaviest of these schedules (Proposition 19).

Thus, \( W_k(s, e, \sigma, \varepsilon) \geq W' \).

We now prove that, if one of the four conditions holds then \( W_k(s, e, \sigma, \varepsilon) \geq W_{k-1}(s, e, \sigma, \varepsilon) \). According to Proposition 20, there is a feasible schedule for \( k, s, e, \sigma \) in which \( J_k \) is not processed in \([s, e]\). Note that \( W_{k-1}(s, e, \sigma, \varepsilon) \) is the weight of the heaviest of these schedules. Hence, \( W_k(s, e, \sigma, \varepsilon) \geq W_{k-1}(s, e, \sigma, \varepsilon) \).

We now prove that \( W_k(s, e, \sigma, \varepsilon) \leq \max(W', W_{k-1}(s, e, \sigma, \varepsilon)) \). Consider a schedule that realizes \( W_k(s, e, \sigma, \varepsilon) \). Either \( J_k \) is processed in \([s, e]\) and thus \( W_k(s, e, \sigma, \varepsilon) = W' \) or it is not and thus \( W_k(s, e, \sigma, \varepsilon) = W_{k-1}(s, e, \sigma, \varepsilon) \) (cf. Proposition 19 and 22). Hence, \( W_k(s, e, \sigma, \varepsilon) \) is lower than or equal to \( \max(W', W_{k-1}(s, e, \sigma, \varepsilon)) \).

Finally, notice that if none of the four conditions holds then \( J_k \) is processed in \([s, e]\) in any feasible schedule for \( k, s, e, \sigma \) (Proposition 21). Thus, \( W_k(s, e, \sigma, \varepsilon) = W' \).

3.3.5 A Dynamic Programming Algorithm

As shown in § 3.3.4, the maximum weighted number of early jobs is exactly \( W_n(\min(\Theta), \max(\Theta), 0, \varepsilon_0) \). It can be dynamically computed thanks to the decomposition scheme (Theorem 23). Algorithm 3 is a straightforward implementation of this scheme: Given a combination of the parameters \( k, s, e, \sigma, \varepsilon \), the value of \( W_k(s, e, \sigma, \varepsilon) \) is recursively computed (lines 6–27). Note that Algorithm 3 relies on Definition 9 for the initialization part: \( W_0(s, e, \sigma, \varepsilon) = 0 \). This is omitted in the pseudo-code. To simplify the presentation, we use \( \sigma \) and \( \varepsilon \) in the expressions \( W_{k-1}(s, t, \sigma, \tau) \) (line 12) and \( W_{k-1}(s, e, \sigma, \varepsilon) \) (line 26) while it would be more appropriate to refer to the restriction of \( \sigma \) and \( \varepsilon \) to the \( k-1 \) first jobs. Note that the algorithm does not try to reach a value of \( W \) (lines 12, 26) that has not been previously computed.

We do not have to consider all possible combinations of the parameters (lines 1–6) and we only focus on “non-dominated” combinations \( k, s, e, \sigma, \varepsilon \), i.e., combinations where \( s, e \in \Theta, \sigma \in \Psi_k^{m^2-1}(s) \) and \( \varepsilon \in \Psi_{k+1}^m(e) \). Note that according to Definition 12, \( \Psi_n^{m^2-m+1}(\min(\Theta)) \) contains the function \( \Psi_n^{m^2-m+1}(\min(\Theta)) \) which \( W_n(\min(\Theta), \max(\Theta), 0, \varepsilon_0) \) is non-dominated and thus the algorithm computes \( W_n(\min(\Theta), \max(\Theta), 0, \varepsilon_0) \). It is correct to restrict the search to non-dominated combinations because, in the recursion formula of Theorem 23, all combinations that are examined are non-dominated: Given the definition of \( W' \) (Equation 3.17), it is easy to check that \( k-1, s, t, \sigma, \tau \) and \( k, t+1, e, \tau', \varepsilon \) are non-dominated combinations.

Each function \( \psi \in \Psi_k^l(t) \) can be encoded as an array of size \( n \) that provides the value taken by the function over each job. It can also be encoded as an array of size \( 2l \) that provides the indices of the jobs for which \( \psi(J_i) > 0 \) and the corresponding values \( \psi(J_i) \) (this encoding relies on the fact
that less than \( l \) jobs are such that \( \psi(J_i) > 0 \). We will rely on the second implementation because the relevant values of \( l \) (\( l = m^2 - m + 1 \) and \( l = m^2 + 1 \)) do not depend on \( n \) and therefore the overall encoding of a function requires a constant amount of space. Recall that in each set there are \( O(nm^2 + 1) \) functions. Since \(|\Theta| = O(n^2)\), the space required to store all functions is \( O(nm^2 + 3)\).

We will store the values \( W_k(s, e, \sigma, \varepsilon) \) in a multi-dimensional array. Actually, for each value of \( s \) and \( e \), the functions of \( \Psi_k^{m^2 - m + 1}(s) \) and of \( \Psi_k^{m^2 + 1}(e) \) can be indexed (there are, respectively, \( O(nm^2 - m + 1) \) and \( O(nm^2 + 1) \) such functions). The index can then be used to store \( W_k(s, e, \sigma, \varepsilon) \) in an array \( W[k][i_s][i_e][i_\sigma][i_\varepsilon] \):

- where \( i_s \) is the index of \( s \) in \( \Theta \),
- where \( i_e \) is the index of \( e \) in \( \Theta \),
- where \( i_\sigma \) is the index of \( \sigma \) in \( \Psi_k^{m^2 - m + 1}(s) \),
- where \( i_\varepsilon \) is the index of \( \varepsilon \) in \( \Psi_k^{m^2 + 1}(e) \).

The size of the array \( W \) is therefore \( O(nm^2n^2n^{m^2 + 1}n^{m^2 - m + 1}) = O(n^{2m^2 - m + 7}) \).

It is now easy to compute the time-complexity of the algorithm:

- there are \( n \) possible values for \( k \) (line 1),
- there are \( O(n^2) \) possible values for \( s \) (line 2),
- there are \( O(n^2) \) possible values for \( e \) (line 3),
- there are \( O(n^{m^2 - m + 1}) \) functions \( \sigma \) (line 4),
- there are \( O(n^{m^2 + 1}) \) functions \( \varepsilon \) (line 5),
- there are \( O(n^2) \) possible values for \( t \) distinct values (line 7),
- there are \( O(n^{m^2 - m + 1}) \) functions \( \tau' \) (line 8),
- there are at most \( n^{m-1} \) subsets \( V \) (line 9),
- finding the function \( \tau \) (i.e., the index of the function) may require to browse the whole set \( \Psi_k^{m^2 + 1}(t) \); which may requires \( O(n^{m^2 + 1}) \) steps (line 11).

This leads to an overall complexity of \( O(n^{4m^2 - m + 10}) \). Note that the algorithm is still valid when weights take non-integer values.

### 3.3.6 Open Problems

For any fixed value of \( m \), the parallel machine problem can be solved in \( O(n^{4m^2 - m + 10}) \). The optimal solution is transformed into the optimum solution of the open-shop problem in \( O(mn \log^7(mn)) \) (cf., § 3.3.2). Hence, the problem \( Om|\pi_{ij} = 1, r_i| \sum w_i U_i \) is solvable in polynomial time. The very high time and space complexity of the algorithm that we have presented, make it hardly usable in practice. We think that the complexity could be slightly decreased by using some additional data structures. However, this would not make the algorithm more usable in practice and it would make the algorithm much more complex.

An interesting open question concerns the status of the same UET open-shop problems with other criteria, such as the weighted flow time or the weighted tardiness. A straight generalization of our algorithm is not possible because the dominance property of Proposition 14, based upon an exchange argument, would not hold.

50 Scheduling Equal Length Jobs on Parallel Machines
Chapter 4

Scheduling Equal Length Multiprocessor Tasks

We study the situation where a set of $n$ tasks has to be scheduled on $m$ parallel processors. In most of the classical scheduling models, it is assumed that each task is processed on one processor (also called a machine) at a time. However, the relatively recent development of multiprocessor computer systems and of complex manufacturing environments has led researchers to study more complex situations where each task requires simultaneously several processors (see for instance [35, 88]).

In this chapter we consider a particular multiprocessor scheduling environment where, for each task $i$, a fixed number $\text{size}_i$ of processors is required to execute the task. Yet, the processors required are not specified. Following the classical scheduling notation (see for instance [35, 38]), the corresponding scheduling problems are referred to as $P|\text{size}_i|F$. See Figure 4.1 for an instance of $P|r_i, \text{size}_i|C_{\text{max}}$.

When tasks have identical processing times, the multiprocessor problem $P_m|\text{size}_i, p_i = p|F$ is solvable in polynomial time for $F \in \{\sum w_iC_i, \sum w_iU_i, \sum T_i\}$ (see [48] for a review). When the number of processors is not fixed (i.e., $m$ is a data), the $C_{\text{max}}$ and $\sum C_i$ problems are binary NP-Hard ([160] and [89]). So, $P_m|\text{size}_i, p_i = p|\sum w_iT_i$ is the only remaining open question.

With identical processing times and arbitrary release dates, the situation is more complex. Of course, $P_m|r_i, \text{size}_i, p_i = p|C_{\text{max}}$, as the counterpart of $P_m|\text{size}_i, p_i = p|L_{\text{max}}$, is solvable in polynomial time. Moreover, a linear time algorithm is proposed in [48] for $P_2|r_i, \text{size}_i, p_i = p|\sum C_i$ and it is conjectured that the 3-machine problem is polynomial.

In this Chapter, we first show (Section 4.1) that Brucker, Knust, Roper and Zinder’s conjecture holds for any number of machines: $P_m|r_i, \text{size}_i, p_i = p|\sum C_i$ can be solved in polynomial time by dynamic programming. Then we study the unit execution time problem ($p_i = 1$) and we show that the minimum maximal tardiness can be computed in polynomial time when $\text{size}_i \in \{1, m\}$ (Section 4.2). In this problem, there are no more than two possible sizes, either 1 (small tasks) or $m$ (tall tasks), and we will refer to it as the “tall/small” problem.
4.1 Minimizing Total Completion Time, $Pm|r_i, p_i = p, size_i|\sum C_i$

We introduce an algorithm for $Pm|r_i, p_i = p, size_i|\sum C_i$ and $Pm|r_i, p_i = p, size_i|C_{\text{max}}$. A dominance property is introduced in Section 4.1.1. In Section 4.1.2, we define the variables of the dynamic programming algorithm. The algorithm itself is described in Section 4.1.3.

4.1.1 Dominance Property

From now on let $F$ be the objective function (either $C_{\text{max}}$ or $\sum C_i$) and assume that tasks are sorted in non-decreasing order of release dates, i.e., $r_1 \leq r_2 \ldots \leq r_n$. Proposition 24 is a strong dominance property for optimal schedules.

**Proposition 24.** There is an optimal schedule in which, for any pair of tasks $i, j$ with identical size, $i < j \Rightarrow C_i \leq C_j$.

**Proof.** Consider an optimal solution for $F$ that lexicographically minimizes the vector of completion times $(C_1, \ldots, C_n)$. Assume that there are two tasks $i, j$ with $size_i = size_j$, $i < j$ and $C_i > C_j$. Let us exchange $i$ and $j$. Since $i < j \Rightarrow r_i \leq r_j$, the exchange does not violate the release dates. It is easy to see that this exchange does not modify the objective function $F$ (because $F = C_{\text{max}}$ or $F = \sum C_i$). So we have an optimal schedule with a lexicographically smaller vector of completion times. This contradicts our hypothesis. \qed

4.1.2 Variables Definition

We use dynamic programming to compute the optimal schedule. Each sub-problem is defined by two tuples of $m$ variables: processors variables $(t_1, \ldots, t_m)$ and tasks variables $(i_1, \ldots, i_m)$.

- **Processors variables** $(t_1, \ldots, t_m)$ represent the availability of the processors: No processor is available before $t_1$, 1 processor is available between $t_1$ and $t_2$, 2 processors are available between $t_2$ and $t_3$, $\ldots$, $m$ processors are available after $t_m$ (see Figure 4.2).

- **Tasks variables** $(i_1, \ldots, i_m)$ define the subset of the tasks that are considered in the sub-problem (the other ones have already been scheduled): For a given size $s$, we only consider tasks of this size with $i \geq i_s$. In other words, the tasks of the sub-problem are exactly

$\bigcup_{s=1}^{m} \{i|i \geq i_s, size_i = s\}$.

![Figure 4.2: Processors Variables](image)

To simplify the presentation of the algorithm, we assume that the processors variables are such that $t_1 \leq t_2 \leq \ldots \leq t_m$ and $t_m - t_1 \leq p$. In the following we will see that this assumption always holds at any step of the algorithm.

Processors variables together with tasks variables define a sub-problem. Five sub-problems are depicted in Figure 4.3. For each of them we have a partial schedule made of tasks that have already been scheduled. The tasks of the sub-problem are those that are not scheduled yet. They have to be scheduled after the “thick border line” defined by the processors variables.
In the following, \( F(t_1, \ldots, t_m, i_1, \ldots, i_m) \) denotes the optimal value of the objective function for the corresponding sub-problem. Note that the optimum of our initial problem is exactly
\[
F(\min_i r_i, \ldots, \min_i r_i, 0, \ldots, 0).
\]

### 4.1.3 Dynamic Programming

Consider an optimal non-dominated active schedule of the sub-problem and assume that \( s \) is the size of one of the tasks of the sub-problem with minimal completion time (in the schedule of Figure 4.1, \( s = 4 \)). Since the tasks of size \( s \) are exactly \( \{i| i \geq i_s, \text{size}_i = s\} \) and since completion times of the tasks of the same size are non-decreasing (Proposition 24), we know that the task \( x = \min\{i|i \geq i_s, \text{size}_i = s\} \) is a task with minimum completion time.

We distinguish two cases to recursively compute \( F(t_1, \ldots, t_m, i_1, \ldots, i_m) \). First, if \( t_1 < r_x \) then at least one processor is available before \( r_x \). Since no task starts before \( r_x \) (otherwise the completion time of \( x \) would not be minimal), the processors variables can be “increased” so that no processor is available before \( r_x \). Second, if \( t_1 \geq r_x \) then \( x \) starts exactly at time \( t_s \) and we will see how tasks and processors variables can be computed.

**CASE 1:** \( t_1 < r_x \).

Since no task starts before \( r_x \) (otherwise the completion time of \( x \) would not be minimal), the objective function \( F(t_1, \ldots, t_m, i_1, \ldots, i_m) \) equals
\[
F(\max(t_1, r_x), \ldots, \max(t_m, r_x), i_1, \ldots, i_m).
\] (4.1)

Note that we have \( \max(t_1, r_x) \leq \max(t_2, r_x) \leq \ldots \leq \max(t_m, r_x) \) and that \( \max(t_m, r_x) - \max(t_1, r_x) \leq p \). Hence, the two initial assumptions on the processors variables still hold.

**CASE 2:** \( r_x \leq t_1 \).

Task \( x \) starts exactly at time \( t_s \) and is completed at \( t_s + p \). The new tasks variables are \( (i_1, \ldots, i_{s-1}, x + 1, i_{s+1}, \ldots, i_m) \). Let us compute the new processors variables. Task \( x \) is completed at \( t_s + p \) and the \( s \) processors that were used to execute the tasks are available again. The \( s \) processors that used to be available at \( t_s \) are now available at \( t_s + p \) and nothing changes for the \( m - s \) other processors. Since \( t_m - t_1 \leq p \), the new processors variables are exactly
\[
(t_s + 1, \ldots, t_m, t_s + p, \ldots, t_s + p).
\]

It is easy to see that \( (t_s + p) - t_{s+1} \leq p \) and consequently, the difference between the last and the first processor variable is still lower than or equal to \( p \). Hence, the two initial assumptions on the processors variables still hold.

For the \( C_{\max} \) criterion, \( F(t_1, \ldots, t_m, i_1, \ldots, i_m) \) equals
\[
F(t_{s+1}, \ldots, t_m, t_s + p, \ldots, t_s + p, i_1, \ldots, i_{s-1}, x + 1, i_{s+1}, \ldots, i_m).
\] (4.2)

For the \( \sum C_i \) criterion, \( F(t_1, \ldots, t_m, i_1, \ldots, i_m) \) equals
\[
F(t_{s+1}, \ldots, t_m, t_s + p, \ldots, t_s + p, i_1, \ldots, i_{s-1}, x + 1, i_{s+1}, \ldots, i_m) + t_s + p.
\] (4.3)

So, if we know the size \( s \) of the task of the sub-problem with minimal completion time, then, thanks to (4.1), (4.2) and (4.3), we can recursively compute the optimum value of \( F(t_1, \ldots, t_m, i_1, \ldots, i_m) \). Since \( s \) is not known in advance, all possible values are tried and the one leading to the best solution is chosen. On the example of Figure 4.3, we can see that the left sub-problem leads to 4 sub-problems (one for each possible size). The last one only corresponds to CASE 1.

Note that the variables \( t_i \) can take any integer value. Hence, there is not a polynomial number of states and thus our dynamic programming scheme is not likely to run in polynomial time. However, it’s easy to see that on an active schedule, start times equal a release date modulo \( p \). More precisely, tasks start and are completed in
\[
\Theta = \{t \mid \exists r_i, \exists l \in \{0, \ldots, n\}, t = r_i + lp\}.
\]
s = 1 (thus, x = 4) CASE 2 of the recursion

s = 2 (thus, x = 6) CASE 2 of the recursion

s = 3 (thus, x = 2) CASE 2 of the recursion

s = 4 (thus, x = 7) CASE 1 of the recursion

Figure 4.3: The Dynamic Scheme
in polynomial time. Two algorithms are described. The first one is based on a linear programming formulation of the problem while the second one is a combinatorial algorithm. The complexity status of this tall/small task scheduling problem is NP-Hard in the strong sense [160]. Both problems can be solved using dynamic programming. However, the arbitrary size problem is NP-Hard in the strong sense.

Algorithm 4 is a straight implementation of the decomposition rules for $C_{\text{max}}$ (for $\sum C_i$, lines 6 and 16 have to be changed respectively into $F(t_1, \ldots, i, \ldots, i_m) = 0$ and $F_s^* \rightarrow F(t_{s+1}, \ldots, t_m, t_s + p, \ldots, t_s + p, i_1, \ldots, i_{s-1}, x + 1, i_{s+1}, \ldots, i_m) + t_s + p$). Before describing Algorithm 4, we need to introduce the notation $N(u, z)$, the smallest index greater than $u$ among tasks of size $z$ (i.e., $N(u, z) = \min \{i | i \geq u, \text{size}_i = z\}$). If such a task does not exist, $N(u, z)$ is set to a special negative value. Note that $N(u, z)$ can be pre-computed in linear time. Now, let us examine Algorithm 4.

- We iterate over all tasks and processors variables sorted in decreasing lexicographical order (lines 1–4). This ordering ensures that the optima of all sub-problems of the current sub-problem have already been computed.

- If the set of tasks of the sub-problem $\bigcup_{s=1}^{m} \{i | i \geq i_s, \text{size}_i = s\}$ is empty (line 5) then $F(t_1, \ldots, i_1, \ldots, i_m)$ equals $t_m$.

- If the set of tasks of the sub-problem is not empty, we iterate over all possible sizes $s$ of the tasks of the sub-problem (lines 9–10). For each $s$, $F_s^*$, the optimum of the sub-problem, under the hypothesis that first task to execute has size $s$, is computed (lines 12–13 and 14–20 respectively correspond to CASE 1 and CASE 2).

- If $t_s + p \notin \Theta$ (line 18) then we are building a non-active schedule so, $F_s^*$ can be set to $\infty$.

- If $t_s + p \in \Theta$ (line 15) then $(t_{s+1}, \ldots, t_m, t_s + p, \ldots, t_s + p)$ is a relevant combination of processors variables and we can apply the recursion.

- $F(t_1, \ldots, t_m, i_1, \ldots, i_m)$ equals the minimum of $F_s^*$ over all possible sizes $s$ of the tasks of the sub-problem (line 21).

There are $O(n^2m)$ possible tuples of processors variables and $O(n^m)$ tuples of tasks variables to consider. So we have $O(n^{3m})$ combinations of variables for which $F$ has to be computed. Since $m$ is fixed, for each combination (lines 5–24), $F$ is computed in constant time. Hence, the algorithm runs in $O(n^{3m})$.

4.1.4 Open Questions

We have shown that $Pm|r_i, p_i = p, \text{size}_i|\sum C_i$ can be solved in polynomial time. The same algorithm can be used to minimize $C_{\text{max}}$. We do not think that our algorithm is likely to be generalized to handle other criteria and so, the complexity status of the weighted completion time problem is still an open question.

4.2 Scheduling Tall/Small Tasks, $P|r_i, p_i = 1, \text{size}_i \in \{1, m\}|\text{L}_{\text{max}}$

We study the scheduling situation where $n$ tasks, subjected to release dates and due dates, have to be scheduled on $m$ parallel processors. We show that, when tasks have unit processing times and either require 1 or $m$ processors simultaneously, the minimum maximal lateness can be computed in polynomial time. Two algorithms are described. The first one is based on a linear programming formulation of the problem while the second one is a combinatorial algorithm. The complexity status of this “tall/small” task scheduling problem $P|r_i, p_i = 1, \text{size}_i \in \{1, m\}|\text{L}_{\text{max}}$ was unknown before, even for 2 processors.

When all release dates are equal, the arbitrary size problem for any fixed number of processors, denoted $Pm|p_i = 1, \text{size}_i|T_{\text{max}}$, can be solved in polynomial time [50]. Similarly, the problem for any fixed number of sizes, denoted $P|p_i = 1, |\{\text{size}_i\}| = c|T_{\text{max}}$, can be solved in polynomial time. Both problems can be solved using dynamic programming. However, the arbitrary size problem is NP-Hard in the strong sense [160].

22: end if
23: end for
24: end if
25: end for
26: end for
When preemption is allowed, even with arbitrary processing times and release dates, the very general problem $Pm|r_i, size_i, pmtn|T_{\text{max}}$ problem is easy to solve. Existing algorithms are based on a Linear Programming formulation where a variable is associated to each subset of tasks whose total resource requirement is less than $m$ (see for instance [35]). Unfortunately, there are some instances of $P|r_i, p_i = 1, size_i \in \{1, m\}|L_{\text{max}}$ for which the non-preemptive maximum lateness is strictly larger than the preemptive maximum lateness. In the preemptive schedule of Figure 4.4, $L_{\text{max}} = 0$, while the value of $L_{\text{max}}$ is at least 1 for any non-preemptive schedule.

![Figure 4.4: An optimal preemptive schedule.](image)

In the following, we focus on the decision variant of the maximal lateness problem. For a fixed value of $L_{\text{max}}$, it is easy to compute a deadline $d_i = d_i + L_{\text{max}}$ for each task $i$ and a schedule is said to be feasible if tasks are completed before their deadlines. To compute the minimal maximal lateness, one can find the smallest value of $L_{\text{max}}$ for which there is a feasible schedule. Since one can easily build a feasible schedule with $L_{\text{max}} = n$, there are no more than $n$ values to test. A dichotomic search could be used to reduce the number of iterations. So, the $L_{\text{max}}$ problem can be solved in polynomial time provided that the deadline scheduling problem is solvable in polynomial time.

In Section 4.2.1, we introduce a linear programming formulation of the problem and in Section 4.3 we describe a combinatorial algorithm to solve the problem. Finally we draw some conclusions in Section 4.3.1.

### 4.2.1 An LP Formulation

In Section 4.2.2 we describe some linear constraints that must be met by any feasible schedule. In Section 4.2.3 we show that if these constraints hold, we can build a preemptive schedule of tall tasks that “implicitly” takes into account the small tasks. This schedule is transformed in Section 4.2.4 into a non-preemptive schedule of both small and tall tasks.

### 4.2.2 Necessary Conditions

To simplify the presentation of the algorithm we will introduce some time indexed variables. There are few relevant time points so the total number of variables remains polynomial in $n$. Indeed, we can assume that the distance between two consecutive release dates $r_x, r_y$ is not larger than $n$ (otherwise, the tasks could be split in two subsets $\{i: r_i \leq r_x\}$ and $\{i: r_i \geq r_y\}$ that could be scheduled independently). On top of that, we can also assume that the largest deadline is not larger than the largest release date plus $n$. Due to these assumptions, we have a polynomial number of relevant integer time points $t$ to consider. In the following, unless precisely stated, time points and time slots are integral.

Consider a feasible schedule and, for each tall task $i$ and for each integer time point, let $t$, $x^t_i \in [0, 1]$ be the total time during which $i$ executes in the time-slot $[t, t+1)$. Each tall task has to be scheduled somewhere between its release date and its deadline so,

$$\forall i \in T_m, \sum_{t=r_i}^{d_i-1} x^t_i = 1. \quad (4.4)$$
On top of that, the total time during which tall tasks are processed in a single time slot does not exceed the size of the time slot, i.e.,
\[ \forall t, \sum_{i \in T_m} x^t_i \leq 1. \]  

(4.5)

Now let us focus on small tasks. For any time interval \([t_1, t_2]\), let \(T_1(t_1, t_2)\) be the set of small tasks that have to execute in the time interval \([t_1, t_2]\), i.e.,
\[ T_1(t_1, t_2) = \{ i \in T_t : t_1 \leq r_i < d_i \leq t_2 \}. \]

Note that in a non-preemptive schedule, \(q\) small tasks cannot be scheduled in less than \(\lceil \frac{d_1}{m} \rceil\) time units. Since in a time interval \([t_1, t_2]\) there are only \(t_2 - t_1 - \sum_{i \in T_m} \sum_{t=t_i}^{t_2-1} x^t_i\) time units available to schedule tall tasks, we get
\[ \forall [t_1, t_2), \sum_{i \in T_m} \sum_{t=t_i}^{t_2-1} x^t_i + \left\lceil \frac{|T_1(t_1, t_2)|}{m} \right\rceil \leq t_2 - t_1. \]

(4.6)

Hence, if there is feasible schedule, there is a feasible solution of the Linear Program (4.7).

\[
\begin{align*}
\forall i \in T_m, \sum_{t=r_i}^{d_i-1} x^t_i &= 1 \\
\forall t, \sum_{i \in T_m} x^t_i &\leq 1 \\
\forall [t_1, t_2), \sum_{i \in T_m} \sum_{t=t_i}^{t_2-1} x^t_i + \left\lceil \frac{|T_1(t_1, t_2)|}{m} \right\rceil &\leq t_2 - t_1 \\
\forall i \in T_m, \forall t, x^t_i &\geq 0
\end{align*}
\]

(4.7)

In the following, we show that a feasible schedule exists if there is a feasible solution of (4.7).

4.2.3 Preemptive Schedule of Tall Tasks

From now on, we assume that tasks \(1, \ldots, |T_m|\) are the tall ones and that they are sorted in non-decreasing order of due dates, i.e., \(d_1 \leq \ldots \leq d_{|T_m|}\).

A solution \(x\) of (4.7), specifies the duration \(x^t_i\) a tall task \(i\) is scheduled in \([t, t+1)\). To precisely build a preemptive schedule of tall tasks, it remains to decide how pieces of tall tasks are scheduled inside each time slot \([t, t+1)\). Let \(S(x)\) be the schedule where, in each time slot, pieces of tall tasks are scheduled from left to right according to their initial numbering (i.e., in non-decreasing order of deadlines). Now let us consider the solution \(\bar{x}\) that lexicographically minimizes the vector of average completion times \((C_1, \ldots, C_{|T_m|})\), where \(C_i = \sum_{t=r_i}^{d_i-1} t \cdot x^t_i\). The next proposition shows that in any such solution \(x^t_i\) is either 0 or 1.

**Proposition 25.** In \(S(\bar{x})\) tall tasks are not preempted and they start at integer time points.

**Proof.** Let \(k\) be the first task for which the proposition does not hold (all tasks with smaller indices are not preempted and start at integer time points). Let \([t, t+1)\) and \([t', t'+1)\) be the time slots in which \(k\) respectively starts and is completed in \(S(\bar{x})\).

First, we show that in \([t, t+1)\), \(k\) is the only tall task to execute. Indeed, if there was another tall task \(l\) that executes there, we would have \(l > k\) (because of our assumption on \(k\)). Therefore, we could exchange a small piece of \(l\) that executes in \([t, t+1)\) with a small piece of \(k\) that executes in \([t', t'+1)\). In other terms, we could build a vector \(\tilde{x}\) that equals \(\bar{x}\) except for the following values:

\[
\begin{align*}
\tilde{x}^t_k &= \bar{x}^t_k + \varepsilon \\
\tilde{x}^{t'}_k &= \bar{x}^{t'}_k - \varepsilon \\
\tilde{x}^t_l &= \bar{x}^t_l + \varepsilon \\
\tilde{x}^{t'}_l &= \bar{x}^{t'}_l - \varepsilon
\end{align*}
\]

where \( \varepsilon = \min\{\bar{x}_k^t, \bar{x}_k^t\} > 0 \). In the resulting schedule \( S(\bar{x}) \) the average completion time of \( k \) is smaller than its average completion time in \( S(\bar{x}) \) and task \( l \) is completed before its deadline (because \( \bar{d}_l \geq \bar{d}_k \)). Moreover, the “load” of each time slot \([\tau, \tau + 1)\) is the same in both schedules, i.e.,

\[
\forall \tau, \sum_{i \in T_m} \bar{x}_i^\tau = \sum_{i \in T_m} \bar{x}_i^\tau.
\]

It follows that \( \bar{x} \) is a feasible solution of (4.7) and it is smaller lexicographically than \( \bar{x} \). This contradicts our hypothesis on \( \bar{x} \).

Second, note that some constraints of (4.7) must be tight for \( \bar{x} \) and prevent us from increasing \( \bar{x}_k^t \) by \( \varepsilon \) and decrease \( \bar{x}_k^t \) by \( \varepsilon \). Indeed, if we could perform this exchange, we would obtain a “lower” feasible solution in the lexicographical order we defined. Constraints (4.4) do not prevent us from making this exchange. Neither do Constraints (4.5) since \( k \) is the only tall task to execute in time slot \( t \). Now, let us examine Constraints (4.6). We are going to show that a slightly more complex exchange is possible. In the following, the notation \( \mathcal{I}(t_1, t_2) \) refers to the constraint (4.6) over the interval \([t_1, t_2)\). Let \( \Omega \) be the set of constraints (4.6) with \( t_1 \leq t \) and \( t < t_2 \leq t' \) that are tight for \( \bar{x} \).

It is easy to see that Constraints (4.6) that do not belong to \( \Omega \) do not prevent us from increasing \( \bar{x}_k^t \). Among the constraints of \( \Omega \) let us pick one with maximum \( t_1 \). Since the constraint is tight, we have

\[
\sum_{i \in T_m} \sum_{t=t_1}^{t_2-1} \bar{x}_i^t = t_2 - t_1 - \left\lfloor \frac{|\mathcal{I}(t_1, t_2)|}{m} \right\rfloor.
\]

Hence, \( \sum_{i \in T_m} \sum_{t=t_1}^{t_2-1} \bar{x}_i^t \) takes an integer value and consequently, there is another tall task \( u \) that is partially executed between \( t_1 \) and \( t_2 \). If \( u \) were partially executed between \( t \) and \( t_2 \) then we could exchange a piece of it with the last piece of \( k \) that executes in \([t', t' + 1)\) (we have \( \bar{d}_u \geq \bar{d}_k \) because \( u \) is preempted and so the exchange is feasible). We would have decreased the average completion time of \( k \); which would contradict our initial hypothesis. So \( u \) is partially executed in a time slot \([\tau, \tau + 1)\) between \( t_1 \) and \( t \). Let \( \bar{x} \) be the vector that equals \( \bar{x} \) except of the following values:

\[
\begin{align*}
\bar{x}_u^\tau &= \bar{x}_u^\tau - \varepsilon \\
\bar{x}_u^{t'} &= \bar{x}_u^{t'} + \varepsilon \\
\bar{x}_k^t &= \bar{x}_k^t - \varepsilon \\
\bar{x}_k^{t'} &= \bar{x}_k^{t'} + \varepsilon
\end{align*}
\]

for a small positive value \( \varepsilon \). Note that a piece of \( u \) can be scheduled at \( t' \) because \( \bar{d}_u \geq \bar{d}_k \). Moreover, the only constraints that could be violated by the exchange are those in the set \( \Omega \) (the value of \( \bar{x}_k^t \) is consistent with (4.5) because \( k \) is the only tall task that executes in \([t, t + 1)\)). Let \( \mathcal{I}(t'_1, t'_2) \) be a violated constraint of \( \Omega \). Because of our hypothesis on \( t_1 \), we have \( t'_1 \leq t_1 \). Hence, it is easy to verify that the load induced by the tall tasks between \( t'_1 \) and \( t'_2 \) does not increase. Therefore, the resulting schedule \( S(\bar{x}) \) is lower than \( S(\bar{x}) \) in the lexicographical order. This contradicts our hypothesis. \( \square \)

### 4.2.4 From Preemptive to Non-Preemptive Schedules

In Section 4.2.3, we have shown that there is a solution \( \bar{x} \) of (4.7) such that in \( S(\bar{x}) \), tall tasks are not preempted and start at integer time points. In Proposition 26 we show that small tasks can be scheduled in \( S(\bar{x}) \) too.

**Proposition 26.** Small tasks can be scheduled in \( S(\bar{x}) \).

**Proof.** Let us sort small tasks in non-decreasing order of deadlines and let us add them one after the other into \( S(\bar{x}) \). Each time, the current task starts at the first time point after its release date where one processor is available. Note that because tall tasks are not preempted and start at integer time points, small tasks are not preempted either and also start at integer time points.

Let \( k \) be the first small task that is completed after its deadline and let \( t \) be the earliest time point such that all processors are full between \( t \) and \( \bar{d}_k \). Note that since \( k \) is not completed by its deadline \( t \leq r_k \). Let \( \Psi \) be the set of small tasks that are scheduled in \([t, \bar{d}_k)\). Tasks in \( \Psi \) have a release
date greater than or equal to \( t \) (otherwise they would be scheduled in \([ t - 1, t ]\)) and a deadline smaller than or equal to \( d_k \) (because tasks are sorted in non-decreasing order of deadlines). Since all processors are full, there are exactly \( m(\bar{d}_k - t - \sum_{i \in T_0} \sum_{t' = t}^{d_i - 1} \bar{x}_{i,t'}) \) tasks in \( \Psi \). On top of that, \( \Psi \subset T_1(t, \bar{d}_k) \) and \( k \notin \Psi \) but \( k \in T_1(t, \bar{d}_k) \). Hence,

\[
T_1(t, \bar{d}_k) > m(\bar{d}_k - t - \sum_{i \in T_0} \sum_{t' = t}^{d_i - 1} \bar{x}_{i,t'}). 
\]

This contradicts (4.6).

\[\Box\]

### 4.3 A Combinatorial Algorithm

For each time interval \([t_1, t_2]\), we define recursively the slack of the interval, denoted \( \Delta(t_1, t_2) \). The slacks can be computed in polynomial time and we show later that there exists a feasible schedule if and only if all the intervals have non-negative slack. Intuitively, \( \Delta(t_1, t_2) \) is an upper bound on the number of free time slots in \([t_1, t_2]\) in any schedule of the tasks in \( T(t_1, t_2) \). (For a given schedule a free time slot is a time unit in which all the \( m \) processors are idle.) To define the slack we define static slack and dynamic slack.

**Definition 14.** For any interval \([t_1, t_2]\), with \( t_2 > t_1 + 1 \), the slack \( \Delta(t_1, t_2) \) is the minimum of the static slack \( \Delta_s(t_1, t_2) \) and of the dynamic slack \( \Delta_d(t_1, t_2) \). For any interval \([t_1, t_2]\), with \( t_1 \leq t_2 \leq t_1 + 1 \), \( \Delta(t_1, t_2) = \Delta_s(t_1, t_2) \).

**Definition 15.** The static slack over \([t_1, t_2]\), \( \Delta_s(t_1, t_2) \), equals

\[
t_2 - t_1 - \left( |T_m(t_1, t_2)| + \left \lfloor \frac{|T_1(t_1, t_2)|}{m} \right \rfloor \right)
\]

**Definition 16.** The dynamic slack over \([t_1, t_2]\), with \( t_2 > t_1 + 1 \), \( \Delta_d(t_1, t_2) \), is the minimum of

\[
\Delta(t_1, t_2') + \Delta(t_1', t_2) - |T_m(t_1, t_2) \setminus (T_m(t_1, t_2') \cup T_m(t_1', t_2))|
\]

over \( t_1', t_2' \) with \( t_1 < t_1' < t_2 < t_2' \).

The next proposition shows that if there is a feasible schedule, then all intervals have non-negative slack.

**Proposition 27.** There are at most \( \Delta(t_1, t_2) \) idle time slots between \( t_1 \) and \( t_2 \) in any feasible schedule of \( T(t_1, t_2) \).

**Proof.** Consider an interval \([t_1, t_2]\) such that there is a feasible schedule of \( T(t_1, t_2) \) with more than \( \Delta(t_1, t_2) \) idle time slots and assume that \( t_2 - t_1 \) is minimal among such intervals. There are \( |T_m(t_1, t_2)| \) tall tasks and \( |T_1(t_1, t_2)| \) small tasks and at least \( \left( |T_m(t_1, t_2)| + \left \lfloor \frac{|T_1(t_1, t_2)|}{m} \right \rfloor \right) \) time units are required to schedule these tasks. It follows that the number of idle time slots in a feasible schedule is no more than the static slack \( \Delta_s(t_1, t_2) \). Hence the slack equals the dynamic slack; that is, \( \Delta(t_1, t_2) = \Delta_d(t_1, t_2) \). Suppose that \( \Delta_d(t_1, t_2) \) is determined by the two time points \( t_1' \) and \( t_2' \); that is, \( \Delta(t_1, t_2) = \Delta(t_1, t_2') + \Delta(t_1', t_2) - |T_m(t_1, t_2) \setminus (T_m(t_1, t_2') \cup T_m(t_1', t_2))| \). Consider the feasible schedule \( S \) of \( T(t_1, t_2) \) and let \( S_r \) and \( S_l \) be the restriction of \( S \) to the tasks of \( T(t_1, t_2') \) and to the tasks of \( T(t_1', t_2) \). The number of idle time slots in \( S \) is less than or equal to the number of those in \( S_l \) plus the number of those in \( S_r \). Given our hypothesis on \( t_2 - t_1 \) this is lower than or equal to \( \Delta(t_1, t_2') + \Delta(t_1', t_2) \). On top of that, large tasks in \( T_m(t_1, t_2) \setminus (T_m(t_1, t_2') \cup T_m(t_1', t_2)) \) are not scheduled in \( S_l \) nor in \( S_r \) so the number of idle time slots in \( S \) is less than or equal to

\[
\Delta(t_1, t_2') + \Delta(t_1', t_2) - |T_m(t_1, t_2) \setminus (T_m(t_1, t_2') \cup T_m(t_1', t_2))|,
\]

which equals \( \Delta(t_1, t_2) \). This contradicts our initial hypothesis.

\[\Box\]
The more complicated part is to show that if there is no feasible schedule then there must be at least one interval with negative slack. In order to prove this we first prove two propositions. In the proofs we consider several instances simultaneously. Given an instance $I$, $\Delta(I, t_1, t_2)$, $\mathcal{T}(I, t_1, t_2)$, $\mathcal{T}_1(I, t_1, t_2)$ and $\mathcal{T}_m(I, t_1, t_2)$ denote the slack and the sets associated to $I$ for a given interval $[t_1, t_2]$. From now on, to simplify notation we also assume that the smallest release time is 0.

**Proposition 28.** Consider an instance $I$, and let $J$ be an instance given by removing a tall task $i$, with $r_i = 0$, if such exists. For all $t < \bar{d}_i$, $\Delta(J, 0, t) = \Delta(I, 0, t)$, and for all $t \geq \bar{d}_i$, $\Delta(J, 0, t) = \Delta(I, 0, t) + 1$.

**Proof.** The first part follows directly from the definition of slack. Consider the second part and to obtain a contradiction assume that the equality does not hold. Let $t$ be the minimum time such that that $\Delta(J, 0, t) \neq \Delta(I, 0, t) + 1$. We first show that $\Delta(J, 0, t) \leq \Delta(I, 0, t) + 1$. We consider two cases.

**Case 1:** $\Delta(I, 0, t) = \Delta_s(I, 0, t)$. Since $\Delta_s(I, 0, t) = \Delta_s(I, 0, t) + 1$, we have $\Delta(J, 0, t) \leq \Delta(I, 0, t) + 1$.

**Case 2:** $\Delta(I, 0, t) = \Delta_d(I, 0, t)$. Let $t_1, t_2$ be two time points that determine $\Delta_d(I, 0, t)$. Note that $\Delta(I, t_1, t) = \Delta(J, t_1, t)$ (because $0 < t_1$). If $\bar{d}_i \leq t_2$ then $i$ does not belong to $\mathcal{T}_m(I, 0, t_2) \cup \{\mathcal{T}_m(I, 0, t_2) \cup \mathcal{T}_m(I, t_1, t)\}$. Hence, the slack of $J$ is not larger than

$$\Delta(J, 0, t_2) + \Delta(I, t_1, t) - |\mathcal{T}_m(I, 0, t_2) \cup \mathcal{T}_m(I, t_1, t)|.$$

Since $t_2 < t$, by our assumption $\Delta(J, 0, t_2) = \Delta(I, 0, t_2) + 1$. Hence, $\Delta(J, 0, t) \leq \Delta(I, 0, t) + 1$. If $\bar{d}_i > t_2$ then

$$\Delta(J, 0, t) \leq \Delta(J, 0, t_2) + \Delta(I, t_1, t) - (|\mathcal{T}_m(I, 0, t_2) \cup \mathcal{T}_m(I, t_1, t)| - 1) = \Delta(I, 0, t) + 1.$$

Similarly, it can be shown that $\Delta(J, 0, t) \leq \Delta(J, 0, t) - 1$, by considering the two cases $\Delta(J, 0, t) = \Delta_s(I, 0, t)$ and $\Delta(J, 0, t) = \Delta_d(I, 0, t)$. 

**Proposition 29.** Consider an instance $I$. Let $k$ be the number of small tasks in $I$ with release date 0. Let $J$ be the instance derived from $I$ by removing $\min\{k, m\}$ small tasks with the smallest deadline among tasks with release date 0, and by changing the release date of the rest of the tasks with release date 0 (if any) to 1. Let $x$ be a tall task in $I$ with the earliest deadline among tall tasks with release date 0 (if such exists), and let $t$ be $\bar{d}_x$ if $x$ is exists and $\infty$ otherwise. For all $1 < t_2 < t$,

$$\min\{\Delta(J, 0, t_2), \Delta(I, 1, t_2)\} \leq \Delta(J, 1, t_2).$$

**Proof.** To obtain a contradiction assume that $t_2$ is the minimum time for which the inequality does not hold. If $k \leq m$ then since there are no tall tasks with release date 0 and deadline at most $t_2$ in $I$, we have $\Delta(J, 1, t_2) = \Delta(J, 1, t_2)$; a contradiction. Suppose that $k > m$. Let $\bar{d}$ be the earliest deadline of a task in $I$ with release date 0 that was not removed. If $t_2 < \bar{d}$ then again $\mathcal{T}(J, 1, t_2)$ does not contain any task with release time 0 in $I$, and thus, $\Delta(I, 1, t_2) = \Delta(J, 1, t_2)$; a contradiction. The only remaining case is $t_2 \geq \bar{d}$. We consider two cases.

**Case 1:** $\Delta(J, 1, t_2) = \Delta_s(J, 1, t_2)$. Since $t_2 \geq \bar{d} |\mathcal{T}_1(J, 1, t_2)| = |\mathcal{T}_1(I, 0, t_2)| - m$ and thus

$$\left\lfloor \frac{|\mathcal{T}_1(J, 1, t_2)|}{m} \right\rfloor = \left\lfloor \frac{|\mathcal{T}_1(I, 0, t_2)|}{m} \right\rfloor - 1.$$

Recall also that since no tall task in $I$ has release date 0 and deadline at most $t_2$ we have for all $1 < s \leq t_2$, $\mathcal{T}_m(I, 0, s) = \mathcal{T}_m(J, 1, s)$. We get

$$\Delta(J, 1, t_2) = t_2 - 1 - (|\mathcal{T}_m(J, 1, t_2)| + \left\lfloor \frac{|\mathcal{T}_1(J, 1, t_2)|}{m} \right\rfloor)$$

$$= t_2 - (|\mathcal{T}_m(I, 0, t_2)| + \left\lfloor \frac{|\mathcal{T}_1(I, 0, t_2)|}{m} \right\rfloor)$$

$$= \Delta_s(I, 0, t_2) \geq \Delta(I, 0, t_2).$$
4.3.1 Open Questions

Case 2: \( \Delta(J, 1, t_2) = \Delta(J, 1, t_2) \). Let \( t'_{1}, t'_{2} \) with \( 1 < t'_{1} < t'_{2} < t_2 \) be time points that determine the dynamic slack. Recall that by our assumption \( \min \{ \Delta(I, 0, t'_{2}), \Delta(I, 1, t'_{2}) \} \leq \Delta(J, 1, t'_{2}) \). Since \( t'_{1} > 1 \), \( \Delta(I, t'_{1}, t_2) = \Delta(J, t'_{1}, t_2) \). We get

\[
\Delta(J, 1, t_2) = \Delta(J, 1, t'_{2}) + \Delta(J, t'_{1}, t_2)
\]

\[
\geq \min \{ \Delta(I, 0, t'_{2}), \Delta(I, 1, t'_{2}) \} + \Delta(J, t'_{1}, t_2)
\]

Proposition 30. If all time intervals have non-negative slack then there is a feasible schedule.

Proof. We prove that if there is no feasible schedule then there must be an interval with a negative slack. Define the size of an instance \( I \) as \( \sum_T \tilde{d}_i - r_i \). We prove it by induction on the size of the instance. The proposition clearly holds for instances of size 1 since such instances consist of one task. Suppose that the proposition holds for all instances of size at most \( s \). We prove it for instances of size \( s + 1 \). Consider an instance \( I \) of size \( s + 1 \) with no feasible schedule. If \( I \) has both a tall task and a small task with release date 0 and deadline 1 or more than \( m \) small tasks with release time 0 and deadline 1 then \( \Delta(I, 0, 1) < 0 \). Suppose that this is not the case. Let \( k \) be the number of small tasks in \( I \) with release date 0. Consider two instances \( J_S \) and \( J_T \) defined as follows. The instance \( J_S \) is derived from \( I \) by removing \( \min \{ k, m \} \) small tasks with the smallest deadline among tasks with release date 0, and by changing the release date of the rest of the tasks with release date 0 (if any) to 1. The instance \( J_T \) is derived from \( I \) by removing a tall task \( x \) with the smallest deadline among tall tasks with release date 0, and by changing the release date of the rest of the tasks with release date 0 (if any) to 1. We assume that the task \( x \) exists. Note that if any of \( J_T \) and \( J_S \) has a feasible schedule then this schedule can be extended to a feasible schedule for \( I \). We conclude that both \( J_S \) and \( J_T \) have no feasible schedule. Since the size of both \( J_S \) and \( J_T \) is at most \( s \), there is an interval with negative slack in both \( J_S \) and \( J_T \). If for \( J \in \{ J_S, J_T \} \), there exists \( 1 < t_1 < t_2 \) such that \( \Delta(J, t_1, t_2) < 0 \) then since \( \Delta(I, 1, t_2) = \Delta(J, t_1, t_2) \) we are done. Suppose that this is not the case. Hence, there are \( t_S, t_T > 1 \) such that \( \Delta(J_S, 1, t_S) < 0 \) and \( \Delta(J_T, 1, t_T) < 0 \). We consider several cases.

Case 1: \( t_R \geq \tilde{d}_x \). Let \( I' \) be the instance given by removing task \( x \) from \( I \). Since the sets of tasks in \( J_T \) and \( I' \) are the same \( \Delta(I', 0, t_T) \leq \Delta(J_T, 0, t_T) - 1 \). By Proposition 28 \( \Delta(I, 0, t_T) = \Delta(I', 0, t_T) - 1 \). Hence, \( \Delta(I, 0, t_T) \leq \Delta(J_T, 1, t_T) < 0 \).

Case 2: \( t_S < \tilde{d}_x \). By Proposition 29 \( \min \{ \Delta(I, 0, t_S), \Delta(I, 1, t_S) \} \leq \Delta(J_S, 1, t_S) < 0 \).

Case 3: The remaining case is \( t_S \geq \tilde{d}_x \) and \( t_T < \tilde{d}_x \). Let \( l \) be the number of large tasks in \( I \) with release date 0 and deadline at most \( t_S \). Let \( J'_S \) be the instance given by removing these \( l \) tasks from \( J_S \). By Proposition 28 \( \Delta(J'_S, 1, t_S) = \Delta(J_S, 1, t_S) + l < 0 \). Let \( I' \) be the instance given by removing these \( l \) tasks from \( I \). Note that \( \Delta(I, 1, t_S) = \Delta(I', 1, t_S) \). By Proposition 29 \( \min \{ \Delta(I', 0, t_S), \Delta(I', 1, t_S) \} \leq \Delta(J'_S, 1, t_S) < 0 \). If \( \Delta(I', 0, t_S) < 0 \) then by Proposition 28 \( \Delta(I, 0, t_S) = \Delta(I', 0, t_S) - l < 0 \). Otherwise, \( \Delta(I, 1, t_S) < 0 \). We get that

\[
\Delta(I, 0, t_S) \leq \Delta(I, 0, t_S) + \Delta(I, 1, t_S) - |T_m(I, 0, t_S) \setminus (T_m(I, 0, t_T) \cup T_m(I, 1, t_S))| < 0 + l - l = 0
\]

To conclude the proof, we just have to consider the situation where the task \( x \) does not exist (i.e., there is no tall task with release date 0). In such a case, the same reasoning as for Case 2 applies.

4.3.1 Open Questions

We have presented two algorithms for scheduling tall/small multiprocessor tasks with unit processing time to minimize maximum tardiness. The first one relies on linear programming and the second
one is purely combinatorial. An interesting open question is whether one of them could be extended to solve a larger class of problem such as $Pm|r_i, p_i = 1, size_i | T_{\text{max}}$. 
Scheduling Equal Length Multiprocessor Tasks
Chapter 5

Batching Equal Length Jobs

We study the situation where \( n \) jobs \( \{ J_1, \ldots, J_n \} \) have to be scheduled on a batching machine. Jobs cannot start before their release dates and all jobs of the same batch start and are completed simultaneously, \( i.e., \) at the starting time (respectively at the completion time) of the batch. Two types of batching machines are studied.

- On a serial batching machine, the length of a batch equals the sum of the processing times of its jobs. When a new batch starts, a constant setup time \( s \) occurs.

- On a parallel batching machine, there are at most \( b \) jobs per batch and the length of a batch is the largest processing time of its jobs. Two situations are often distinguished. The bounded case with \( b < n \) and the unbounded case with \( b = n \). In this environment, no setup is assumed. However, a constant setup time \( s \) could be easily taken into account by increasing of \( s \) the processing time of each job.

Following the notation of [47], these problems are denoted respectively by \( 1|s\text{-}batch, r_i|F, 1|p\text{-}batch, b < n, r_i|F \) (bounded case) and \( 1|p\text{-}batch, r_i|F \) (unbounded case). We refer to [6], [39], [47], [93], [168], [187], [217] for extended reviews on pure batch scheduling problems and on extensions (\( e.g. \) scheduling group of jobs with group-dependent setup times, jobs requiring several machines throughout their execution, \( \text{etc.} \)). Complexity results for problems with identical release dates are summarized in Table 5. The problems \( 1|r_i|F \) are \( \text{NP-Hard} \) for \( L_{\text{max}}, \sum C_i, \sum T_i \), hence the corresponding batching problems \( 1|s\text{-}batch, r_i|F \) and \( 1|p\text{-}batch, r_i|F \) are also \( \text{NP-Hard} \).

These results leave open the status of most of the problems with arbitrary release dates and equal processing times. In this chapter, we first study (Section 5.1) the parallel unbounded problem and we show that, for arbitrary processing times, an optimum schedule can be computed in pseudopolynomial time for any regular objective function. When processing times are equal, the algorithm runs in polynomial time. We then show (Section 5.2) that serial and (bounded) parallel batching problems can be solved in polynomial time for the class of \text{ordered objective functions} (see Definition 2).

5.1 Parallel Unbounded Batching, \( 1|p\text{-}batch, r_i|F \)

We study the parallel unbounded problem \( 1|p\text{-}batch, r_i|F \). From now on, we assume that \( F = \sum f_i \) is regular and that jobs are ordered in non-decreasing order of processing times.

**Proposition 31.** There is an optimal schedule such that, for any batch, the jobs that are smaller than the length of the batch and that are released before or at the starting time of the batch are either executed in the batch or in a previous batch.

**Proof.** Consider a job \( i \) and a batch \( B \) for which the proposition does not hold. The job \( i \) can be moved to \( B \) and since \( F \) is regular, this does not increase the value of objective function. \( \square \)

</table>

Proposition 31 suggests that once the starting time of the largest batch (the one that contains the largest job $n$) is known, we can decompose the problem into two sub-problems that occur before and after this batch.

More formally, a state of the dynamic program is defined by (1) the index $k$ of the largest job considered in the problem, (2) a right fictive batch starting at $s$ with length $\pi_s$ and (3) a left fictive batch starting at $e$ with length $\pi_e \geq p_k$. In the recursion we try to schedule the jobs $i$ with $i \leq k$ and $s < r_i \leq e$ between $s + \pi_s$ and $e + \pi_e$ (jobs can be scheduled either in the right fictive batch or between the fictive batches). Let $F(k, s, \pi_s, e, \pi_e)$ be the minimal cost of such a schedule.

**Proposition 32.** If $r_k > e$ or if $r_k \leq s$ then $F(k, s, \pi_s, e, \pi_e) = F(k - 1, s, \pi_s, e, \pi_e)$ otherwise, $F(k, s, \pi_s, e, \pi_e)$ is the minimum of $F(k - 1, s, \pi_s, e, \pi_e) + f_k(e + \pi_e)$ and of

$$
\min_{t \in [\max(s + \pi_s, r_k), e - p_k]} F(k, s, \pi_s, t, p_k) + F(k, t, p_k, e, \pi_e).
$$

**Proof.** If $r_k > e$ or if $r_k \leq s$ then $k$ is not considered in the sub-problem and hence, $F(k, s, \pi_s, e, \pi_e) = F(k - 1, s, \pi_s, e, \pi_e)$. Now assume that $s < r_i \leq e$ and consider the non-dominated schedule that realizes $F(k, s, \pi_s, e, \pi_e)$. The job $k$ is either scheduled in the right fictive batch or it is scheduled in a batch that starts after or at $s$ and that is completed before or at $e$.

- If $k$ is scheduled in the fictive batch, then the cost of scheduling $k$ is $f_k(e + \pi_e)$ and all other jobs have to be scheduled between $s + \pi_s$ and $e$ or in the fictive batch. So, $F(k, s, \pi_s, e, \pi_e) \geq F(k - 1, s, \pi_s, e, \pi_e) + f_k(e + \pi_e)$.

- If $k$ is scheduled in a batch $B$ starting at $t$ between $s$ and $e$ then, we know that the batch length is $p_k$ (since $k$ is the largest job). Moreover, it has to be completed before $e$ and it cannot start in the left fictive batch so, $t \in [\max(s + \pi_s, r_k), e - p_k]$. According to our dominance property, all other jobs are either executed in batch $B$ or in a previous batch or are released after $t$. Jobs released after $t$ cannot start before the end $t + p_k$ of the batch containing $k$ so, we are exactly in the state $(k, t, p_k, e, \pi_e)$ of the recursion. The other jobs must be completed before or in the batch containing $J_k$ so, we are exactly in the state $(k, s, \pi_s, t, p_k)$. Hence, we have $F(k, s, \pi_s, e, \pi_e) \geq F(k, s, \pi_s, t, p_k) + F(k, t, p_k, e, \pi_e)$. 

We have proven that \( F(k, s, \pi_s, e, \pi_e) \) is greater than or equal to the minimum of \( F(k-1, s, \pi_s, e, \pi_e) \) plus \( f_k(e+\pi_e) \) and of \( \min_{i \in [s+\pi_s,e-p_k]} F(k, s, \pi_s, t, p_k) + F(k, t, p_k, e, \pi_e) \). Now we prove that \( F(k, s, \pi_s, e, \pi_e) \) is lower than or equal to the minimum of the two expressions above.

- First consider a schedule that realizes \( F(k-1, s, \pi_s, e, \pi_e) \). We can add \( k \) in the right fictive batch (the additional cost is \( f_k(e+\pi_e) \)) and we obtain a feasible schedule for the state \((k, s, \pi_s, e, \pi_e)\). So, \( F(k, s, \pi_s, e, \pi_e) \leq F(k-1, s, \pi_s, e, \pi_e) + f_k(e+\pi_e) \).

- Now let \( t \) be the value that realizes \( \min_{i \in [s+\pi_s,e-p_k]} F(k, s, \pi_s, t, p_k) + F(k, t, p_k, e, \pi_e) \) and let us merge the schedules that respectively realize \( F(k, s, \pi_s, t, p_k) \) and \( F(k, t, p_k, e, \pi_e) \). The merging is possible because the right fictive batch of the first one coincides with the left fictive batch of the second one. This schedule is feasible for the state \((k, s, \pi_s, e, \pi_e)\). So, \( F(k, s, \pi_s, e, \pi_e) \leq F(k, s, \pi_s, t, p_k) + F(k, t, p_k, e, \pi_e) \).

If \( P = \sum p_i \) denotes the time horizon, the time complexity of the dynamic programming algorithm is \( O(nP^3) \) since there are \( O(nP^4) \) states and each time the parameter \( t \) can take at most \( P \) values.

Now consider the special case with identical processing times \( \forall i, p_i = p \). First, note that the parameters \( \pi_s \) and \( \pi_e \) become un-useful. Moreover, it is easy to see that there are few relevant starting times since in active schedules, starting times are equal to a release date modulo \( p \). Hence the set of relevant starting times is \( O(n^2) \) and consequently, the complexity of the algorithm reduces to \( O(n^{11}) \).

## 5.2 Batching to Minimize an Ordered Objective Function

From now on, we restrict our study to ordered objective functions \( \sum f_i \) (see Definition 2, Chapter 2). Hence, a kind of due-date \( \delta_i \) is attached to each function \( f_i \) and we have \( \delta_1 \leq \cdots \leq \delta_n \). By analogy with due date scheduling, we say that a job is late when it is completed after \( \delta_i \) and that it is on-time otherwise. The “late” cost is \( \omega_i \) and the early cost is time-dependant. Notice that a late job can be scheduled arbitrary late.

Several dominance properties are stated in §5.2.1. The dynamic programming algorithms for serial and parallel problems are described in §5.2.2 and §5.2.3. Finally in §5.2.4 we show that our approach can be extended to handle \( T_{\text{max}} \) and we draw some conclusions.

### 5.2.1 Dominance Properties

We first define two sets of time points at which batches start on active schedules. We then study a dominance related to ordered objective functions and finally we show that both dominances can be combined.

#### Starting Times

One of the reasons why it is easy to schedule equal length jobs is that there are few possible starting times. Indeed, active schedules are dominant and thus starting times are equal to a release date modulo \( p \). This idea can be extended to batching problems.

#### Serial Batching

Ordered objective functions are regular, hence active schedules are dominant. Consequently, each batch starts either at the release date of one of its jobs or immediately after the completion time of another batch plus the setup time \( s \). Hence we can assume that batches start and end in \( \Theta' \), where

\[
\Theta' = \{ r_\lambda + \mu p + \nu s, \lambda \in \{1, \cdots, n\}, \mu \in \{0, \cdots, n\}, \nu \in \{0, \cdots, n\} \}
\]
Parallel Batching

Because jobs have the same processing time $p$ we can assume that the length of a batch is $p$. On top of that, active schedules are dominant so, batches start and end in $\Theta$ as defined in Proposition 3 ($\Theta = \{t | \exists r_i, \exists t, t_i = r_i + lp\}$).

Notice that $|\Theta'| = O(n^3)$ and $|\Theta| = O(n^2)$.

Ordered Objective Functions

The following proposition holds both for serial and parallel problems.

**Proposition 33.** Any feasible schedule can be transformed in a “better” one where for any pair of on-time jobs $J_u, J_v (u < v)$, being executed in batches starting respectively at $t_u$ and $t_v$, either $t_u \leq t_v$ or $t_v < r_u$.

**Proof.** Sketch. Let $(u, v)$ be the smallest vector, according to the lexicographical order, such that $t_u > t_v$ and $t_v \geq r_u$. The jobs $J_u$ and $J_v$ may be exchanged and the value of the objective function is not increased since it is an ordered objective function. Moreover, it is easy to see that the smallest vector $(u', v')$ that does not satisfy the condition on the new schedule is such that $(u', v') > (u, v)$.

Repeated exchanges can be used to replace any schedule by a schedule which satisfies the condition for all $u, v$ (the vector $(u, v)$ increases at each step, hence the number of exchanges is finite).

Combining All Dominance Properties

Now consider an optimal and active schedule and apply the exchanges of Proposition 33. The resulting schedule is still optimal and the set of starting times is kept the same. Hence we can combine both dominance criteria, i.e., schedules such that

- batches start and are completed either in $\Theta'$ for serial problems, or in $\Theta$ for parallel problems
- and such that for any pair of jobs $J_u, J_v (u < v)$, being executed in batches starting respectively at $t_u$ and $t_v$, either $t_u \leq t_v$ or $t_v < r_u$,

are dominant. In the following such schedules will be referred to as Serial-Dominant or Parallel-Dominant schedules.

5.2.2 Dynamic Programming for the Serial Problem

The dynamic program relies on the notion of partial batch. Usually, once the starting time $t$ and the completion time $t + pv$ of a batch is known, it is easy to compute that $(t + pv - t)/p = \nu$ jobs are in the batch (because the batch is full). In a partial batch, there may be some hole and we only know that at most $(t + pv - t)/p$ jobs are in the batch. The batch is therefore “partial” since some additional jobs could be a priori added. In the following, the maximal number of jobs in a partial batch is denoted by the symbol $\nu$, while $\mu$ denotes the number of jobs actually scheduled.

Before defining the variables of the Dynamic Program, let us introduce the set of jobs $V_k(t_i, t_r)$. For any integer $k \leq n$ and for any time points $t_i \leq t_r$, $V_k(t_i, t_r)$ is the set of jobs whose index is lower than or equal to $k$ and whose release date is in the interval $(t_i, t_r]$.

$$V_k(t_i, t_r) = \{J_i | i \leq k, r_i \in (t_i, t_r] \}$$

Variables of the Dynamic Program

The dynamic search is controlled by 5 parameters $k, t_i, t_r, \nu_i, \nu_r$ and $\mu_r$. Each combination of these parameters defines a sub-problem involving the jobs in $V_k(t_i, t_r)$. As explained below, the objective of the sub-problem is to minimize $\sum_{J_i \in V_k(t_i, t_r)} f_i(C_i)$ under some constraints.

**Definition 17.** A schedule $K$ is Serial-Dominant for $(k, t_i, t_r, \nu_i, \nu_r, \mu_r)$ iff
\( K \) is Serial-Dominant,

- jobs in \( V_k(t_1, t_r) \) are either late or are completed before or at \( t_r + \nu_r \),
- a partial batch, containing 0 job of \( V_k(t_1, t_r) \), starts at \( t_l \) and is completed at \( t_l + \nu_l \),
- a partial batch, containing \( \mu_r \) jobs of \( V_k(t_1, t_r) \), starts at \( t_r \) and is completed at \( t_r + \nu_r \).

Now we can define the variables of the dynamic program.

**Definition 18.** \( S_k(t_1, t_r, \nu_l, \nu_r, \mu_r) \) is the minimal value taken by the function

\[
S_k(t_1, t_r, \nu_l, \nu_r, \mu_r) = \sum_{J_i \in V_k(t_1, t_r)} f_i(C_i)
\]  

over the Serial-Dominant schedules for \( (t_1, t_r, \nu_l, \nu_r, \mu_r) \). If there is no such schedule,

\[
S_k(t_1, t_r, \nu_l, \nu_r, \mu_r) = +\infty.
\]

Given this definition \( S_0(t_1, t_r, \nu_l, \nu_r, \mu_r) \) equals 0 if \( t_l + \nu_l + s \leq t_r \) and \(+\infty\) otherwise.

To get an intuitive picture of the decomposition scheme, assume that \( J_k \in V_k(t_1, t_r) \) is on-time (if it is not, take into account the “late” cost \( f_k(\delta_k) \) and set \( k \) to \( k - 1 \)) and consider the time point \( t \) at which the batch containing \( J_k \) starts on \( K \) (cf. Figure 5.1).

- If \( t = t_r \), i.e., if \( J_k \) is put in the right partial batch, then we take into account the cost \( f_k(t_r + \nu_r) \) associated to \( J_k \) and we solve the sub-problem defined by \( (k-1, t_l, t_r, \nu_l, \nu_r, \mu_r - 1) \).
- If \( t < t_r \), then \( J_k \) is scheduled in an in-between batch starting at \( t \) and containing \( \nu \) jobs.

Thanks to Proposition 33, on-time jobs of \( U_{k-1}(t_1, t) \) are all completed before or at the completion time of this batch. On-time jobs of \( U_{k-1}(t, t_r) \) are completed after this batch. Hence, we have a left sub-problem defined by \( (k-1, t_l, t, \nu, \nu, \mu_r - 1) \) and a right one defined by \( (k-1, t, t_r, \nu, \nu, \mu_r) \).

![Figure 5.1](image.jpg)

Figure 5.1: Two ways to schedule \( J_k \): Either in the right partial batch or in an in-between batch (\( J_k \) can also be late). Ticked boxes in a batch indicate that it is only partially available for the jobs of \( V_k(t_1, t_r) \).

**Fundamental Recursion Formula**

We define three values \( L, R, I \). We will see that they are the costs of optimal schedules where \( J_k \) is in the Left, in the Right or in the In-between batch.

**Definition 19.** \( L \) equals \( S_{k-1}(t_1, t_r, \nu_l, \nu_r, \mu_r) + f_k(\delta_k) \)

**Definition 20.** \( R \) equals \( f_k(t_r + \nu_r) + S_{k-1}(t_1, t_r, \nu_l, \nu_r, \mu_r - 1) \) if \( \mu_r > 0 \) and \(+\infty\) otherwise.
\textbf{Definition 21.} \(I\) is the minimum of

\begin{equation}
S_{k-1}(t_i, t, v_i, \nu, \nu - 1) + f_k(t + \nu) + S_{k-1}(t, t_r, \nu, \nu, \mu_r)
\end{equation}

under the constraints

\begin{equation}
\begin{aligned}
\nu \in \{1, \ldots, n\} \\
t \in \Theta' \\
r_k \leq t \leq \delta_k - p \nu \\
t_r + \nu \delta + s \leq t \leq t_r - p \nu - s
\end{aligned}
\end{equation}

If there are no such \(t\) and \(\nu\), \(I = +\infty\).

The following propositions lead to Proposition 38 that provides the fundamental recursion formula of the dynamic program.

\textbf{Proposition 34.} If \(J_k \in V_k(t_i, t_r)\) then \(S_k(t_i, t_r, v_i, \nu, \mu_r) \leq L\).

\textbf{Proof.} Assume that \(L\) takes a finite value and let \(R\) be the schedule that realizes it. \(R\) is Serial-Dominant for \((k-1, t_i, t_r, v_i, \nu, \mu_r)\) and also for \((k, t_i, t_r, v_i, \nu, \mu_r)\) \((J_k\) is late). The additional cost is exactly \(f_k(\delta_k)\).

\textbf{Proposition 35.} If \(J_k \in V_k(t_i, t_r)\) then \(S_k(t_i, t_r, v_i, \nu, \mu_r) \leq R\).

\textbf{Proof.} Assume that \(R\) takes a finite value and let \(Q\) be the schedule that realizes \(S_{k-1}(t_i, t_r, v_i, \nu, \mu_r - 1)\). Let \(Q'\) be the schedule obtained by adding the job \(J_k\) in the right batch (it can be added because it is released before the starting time of the batch since \(J_k \in V_k(t_i, t_r) \Rightarrow r_k \leq t_r\)). On the new schedule, at most \(\mu_r - 1 + 1 = \mu_r\) jobs of \(V_k(t_i, t_r)\) are scheduled in the right batch. It is easy to verify that \(Q'\) is a Serial-Dominant schedule for \((k, t_i, t_r, v_i, \nu, \mu_r)\). The additional cost is \(f_k(t_r + \nu \mu_r)\). Hence \(S_k(t_i, t_r, v_i, \nu, \mu_r) \leq R\).

\textbf{Proposition 36.} If \(J_k \in V_k(t_i, t_r)\) then \(S_k(t_i, t_r, v_i, \nu, \mu_r) \leq I\).

\textbf{Proof.} Assume that \(I\) takes a finite value and let \(t\) and \(\nu\) be the values that realize 5.2 and meet the constraints 5.3. Let \(K_i\) and \(K_r\) be the schedules that realize respectively \(S_{k-1}(t_i, t, v_i, \nu, \nu - 1)\) and \(S_{k-1}(t, t_r, v_i, \nu, \mu_r)\). We build a schedule \(K'\) by adding the schedules \(K_i\) and \(K_r\) and by adding \(J_k\) in the right batch of \(K_r\). Since the set \(J_k(t_r, t_i)\) is the direct sum of \(J_k(t, t_r)\) plus \(J_k(t_i, t_i)\), all jobs of \(J_k(t_r, t_i)\) are scheduled exactly once on \(K'\). \(J_k\) can be added to the right batch because no more than \(\nu - 1\) jobs are scheduled in this batch on \(K_i\). At least \(s\) time units elapse between batches (because \(t_i + \nu \delta + s \leq t \leq t_r - p \nu - s\)) and it is easy to verify that the in-between batch starts after the release dates of its jobs and before their due dates. We have proven that \(K'\) is feasible.

We claim that \(K'\) is a Serial-Dominant schedule for \((k, t_i, t_r, v_i, \nu, \mu_r)\). We only prove that “for any pair of jobs \(J_u, J_v\), \(J_u(u < v)\), being executed in batches starting respectively at \(t_u\) and \(t_v\), either \(t_u \leq t_v\) or \(t_v < t_u\)”. The verification of all other conditions is easy and is left to the reader. If \(u = k\) and if \(t_v < t_u\) then \(J_u\) belongs to the sub-schedule \(K_r\) and thus, \(J_u \in \hat{U}_{k-1}(t, t_r)\), which leads to \(t = t_v < r_u\) and the condition holds. Now assume that \(u < k\). If both jobs belong to the same sub-schedule either \(K_r\) or \(K_i\), the condition holds because they are Serial-Dominant. Now assume that it is not the case and that \(t_v < t_u\). We know that \(t \in [t_v, t_u)\) and since \(J_u \in \hat{U}_{k-1}(t, t_r)\), \(t_v \leq t < r_u\).

On \(K'\), the batch of \(J_k\) is completed at \(t + \nu r\), hence the total cost of \(K'\) is \(S_{k-1}(t_i, t, v_i, \nu, \nu - 1) + f_k(t + \nu) + S_{k-1}(t, t_r, v_i, \nu, \mu_r) = I\). As a consequence, \(S_k(t_i, t_r, v_i, \nu, \mu_r) \leq I\).

\textbf{Proposition 37.} If \(J_k \in V_k(t_i, t_r)\) then \(S_k(t_i, t_r, v_i, \nu, \mu_r) \geq \min(I, R, L)\).

\textbf{Proof.} We can assume that \(S_k(t_i, t_r, v_i, \nu, \mu_r)\) takes a finite value otherwise the proposition obviously holds. Let \(W\) be the schedule that realizes \(S_k(t_i, t_r, v_i, \nu, \mu_r)\). If \(J_k\) is not scheduled on \(W\), \(i.e.,\) it is late, then \(W\) is also Serial-Dominant for \((k-1, t_i, t_r, v_i, \nu, \mu_r)\) and the cost is decreased of \(f_k(\delta_k)\) (because \(J_k\) is not taken into account). Hence, \(S_k(t_i, t_r, v_i, \nu, \mu_r) \geq L\). Now assume that \(J_k\) is scheduled on-time on \(W\) and let \(t\) be the time point at which the batch containing \(J_k\) starts and let \(\nu\) be the size of this batch.
Hence, if \( J_k \) is scheduled in the last batch, \( i.e., \) if \( t = t_l \), then remove it. It is easy to verify that the resulting schedule is Serial-Dominant for \((k - 1, t_l, t_r, v_l, v_r, \mu_r, -1)\) and its cost is
\[
S_k(t_l, t_r, v_l, v_r, \mu_r) - f_k(t_r + pv_r).
\]
Hence, \( S_{k-1}(t_l, t_r, v_l, v_r, \mu_r - 1) \leq S_k(t_l, t_r, v_l, v_r, \mu_r) - f_k(t_r + pv_r) \). Consequently, \( S_k(t_l, t_r, v_l, v_r, \mu_r) \geq R \).

If \( J_k \) is not scheduled in the last batch then, because of the setup time constraint, it must start after or at \( t + pv_l + s \) and it must be completed before or at \( t - s \). Hence, \( t \in [t_l + pv_l + s, t_r - pv - s] \). Moreover, the batch starts before the release date of \( J_k \) and is completed before its due date. Finally, the batch starts at a time point of \( \Theta' \) because \( \mathcal{W} \) is Serial-Dominant. Hence, constraints 5.3 are met. Let now \( \mathcal{W}_t \) be the sub-schedule obtained from \( \mathcal{W} \) by removing the jobs that are scheduled in batches starting strictly after \( t \) and by removing \( J_k \). This sub-schedule is Serial-Dominant for \((k - 1, t, v_l, v_r, \nu - 1)\) and thus its cost is greater than or equal to \( S_{k-1}(t_l, t, v_l, v_r, 1) \). Similarly, let \( \mathcal{W}_t \) be the sub-schedule obtained from \( \mathcal{W} \) by removing the jobs that are scheduled in a batch starting before or at \( t \). \( \mathcal{W}_t \) is Serial-Dominant for \((k - 1, t, v, v_r, \mu_r)\) and its cost is greater than or equal to \( S_{k-1}(t_l, t, v, v_r, \mu_r) \). Finally, notice that the cost of \( \mathcal{W} \), \( S_k(t_l, t_r, v_l, v_r, \mu_r) \), is the sum of the costs of \( \mathcal{W}_t \) and \( \mathcal{W}_t \) plus the cost of scheduling \( J_k \) in the batch starting at \( t \), \( i.e., \) \( f_k(t + pv) \). Altogether, this leads to \( S_k(t_l, t_r, v_l, v_r, \mu_r) \geq I \).

Hence, \( S_k(t_l, t_r, v_l, v_r, \mu_r) \) is greater than or equal to either \( I, R \) or \( L \).

**Proposition 38.** If \( J_k \in V_k(t_l, t_r) \) then \( S_k(t_l, t_r, v_l, v_r, \mu_r) = \min(I, R, L) \). Otherwise,
\[
S_k(t_l, t_r, v_l, v_r, \mu_r) = S_{k-1}(t_l, t_r, v_l, v_r, \mu_r).
\]

**Proof.** If \( J_k \notin V_k(t_l, t_r) \) then \( V_k(t_l, t_r) = U_{k-1}(t_l, t_r) \) and thus the proposition obviously holds. If \( J_k \in V_k(t_l, t_r) \) then the result comes immediately from Propositions 35, 36 and 37.

**An \( O(n^{14}) \) Algorithm**

There is an optimal schedule that is serial-dominant and it comes directly from the definition of \( S_k(t_l, t_r, v_l, v_r, \mu_r) \) that the optimum is met for
\[
\begin{align*}
  k & := n \\
  t_l & := \min(\Theta') - s - 1 \\
  v_l & := 0 \\
  t_r & := \max(\Theta') + s \\
  v_r & := 0 \\
  \mu_r & := 0
\end{align*}
\]
Notice that if \( s > 0 \) then \( t_l \) can be set to \( \min(\Theta') - s \) instead of \( \min(\Theta') - s - 1 \) because \( U_n(\min(\Theta') - s, \max(\Theta') + s) = \{J_1, \ldots, J_n\} \); which is not the case when \( s = 0 \).

Thanks to Proposition 38, we have a straight dynamic programming algorithm to reach the optimum. The relevant values for \( t_l \) and \( t_r \) are those in \( \Theta' \) plus the special values \( \min(\Theta') - s - 1 \) and \( \max(\Theta') + s \) that are useful to start the dynamic search (to simplify the pseudo-code, these special values have been omitted in Algorithm 5). The relevant values for \( k, v_l, v_r \) and \( \mu_r \) are \( \{0, \ldots, n\} \).

Finally, the values of \( S_k(t_l, t_r, v_l, v_r, \mu_r) \) are stored in a multi-dimensional array of size \( O(n^{10}) \) (\( n \) possible values for \( k, v_l, v_r, \mu_r \), and \( n^3 \) possible values both for \( t_l \) and \( t_r \)).

In the initialization phase, \( S_0(t_l, t_r, v_l, v_r, \mu_r) \) is set to 0 if \( t_l + pv_l + s \leq t_r \) and to a very large value otherwise. The initialization phase runs in \( O(n^3) \) (\( n \) possible values for \( v_l, v_r, \mu_r \), \( n^3 \) possible values both for \( t_l \) and \( t_r \)).

We then iterate on all possible values of the parameters to reach the optimum (cf. Algorithm 5). Each time, a minimum over \( O(n^4) \) terms \( O(n^3) \) for \( t \) and \( O(n) \) for \( v \)) is computed. This leads to an overall time complexity of \( O(n^4) \). A rough analysis of the space complexity leads to an \( O(n^{10}) \) bound but since, at each step of the outer loop on \( k \), one only needs the values of \( S \) computed at the previous step \( (k - 1) \), the algorithm can be implemented with 2 arrays of \( O(n^9) \) size: one for the current values of \( S \) and one for the previous values of \( S \). (To build the optimal schedule, all values of \( S \) have to be kept; hence the initial \( O(n^{10}) \) bound holds.)

5.2.3 Dynamic Programming for the Parallel Problem

Variables of the Dynamic Program

The dynamic search is controlled by 4 parameters $k, t_l, t_r$, and $\mu_r$. Each combination of these parameters defines a sub-problem involving the jobs in $V_k(t_l, t_r)$. The objective is to minimize $\sum_{J_i \in V_k(t_l, t_r)} f_i(C_i)$ under some constraints.

Definition 22. A schedule $K$ is Parallel-Dominant for $(k, t_l, t_r, \mu_r)$ if

- $K$ is Parallel-Dominant,
- jobs in $V_k(t_l, t_r)$ do not start before $t_l + p$,
- jobs in $V_k(t_l, t_r)$ are either late or are completed before or at $t_r + p$,
- a partial batch, containing $\mu_r$ jobs of $V_k(t_l, t_r)$, starts at $t_r$.

Now we can define the variables of the dynamic program.

Definition 23. $P_k(t_l, t_r, \mu_r)$ is the minimal value taken by the function

$$\sum_{J_i \in V_k(t_l, t_r)} f_i(C_i)$$

over the Parallel-Dominant schedules of $V_k(t_l, t_r)$. If there is no such schedule,

$P_k(t_l, t_r, \mu_r) = +\infty$.

Given this definition $P_0(t_l, t_r, \mu_r)$ equals 0 if $t_l + p \leq t_r$ and $+\infty$ otherwise.

To get an intuitive picture of the decomposition scheme, assume that $J_k \in V_k(t_l, t_r)$ is on-time (if it is late, $k$ can be decreased of 1 and we only have to take into account the cost of scheduling $J_k$ late, i.e., $f_k(\delta_k)$) and consider the time point $t$ at which the batch containing $J_k$ starts on $K$ (cf. Figure 5.2).
If $t = t_r$, i.e., if $J_k$ is put in the right batch, we have to solve the same problem with $k := k-1$, $t_l := t_l, t_r := t_r$ and $\mu_r := \mu_r - 1$.

If $t < t_r$, then an in-between batch is created. Thanks to Proposition 33 jobs of $U_{k-1}(t_l, t)$ are either late or are completed before or at the completion time of this batch. Jobs in $U_{k-1}(t, t_r)$ are completed after this batch. Hence, we have two sub-problems. A left one with $(k-1, t_l, t, b-1)$ and a right one with $(k-1, t, t_r, \mu_r)$.

![Diagram](image)

Figure 5.2: Two ways to schedule $J_k$: Either in the right batch or in an in-between batch ($J_k$ can also be late). Ticked boxes in a batch indicate that it is only partially available for the jobs of $V_k(t_l, t_r)$.

**Fundamental Recursion Formula**

Let us redefine the values of $R, I, L$.

**Definition 24.** $L$ equals $P_{k-1}(t_l, t_r, \mu_r) + f_k(\delta_k)$

**Definition 25.** $R$ equals $f_k(t_r + p) + P_{k-1}(t_l, t_r, \mu_r - 1)$ if $\mu_r > 0$ and $+\infty$ otherwise.

**Definition 26.** $I$ is the minimum of

$$P_{k-1}(t_l, t, b-1) + f_k(t + p) + P_{k-1}(t, t_r, \mu_r)$$

under the constraints

$$\begin{cases}
    t \in \Theta \\
    r_k \leq t \leq \delta_k - p \\
    t_l + p \leq t \leq t_r - p
\end{cases}$$

If there is no such $t$, $I = +\infty$.

We are ready to formulate the fundamental proposition.

**Proposition 39.** If $J_k \in V_k(t_l, t_r)$ then $P_k(t_l, t_r, \mu_r) = \min(I, R, L)$. Otherwise,

$$P_k(t_l, t_r, \mu_r) = P_{k-1}(t_l, t_r, \mu_r).$$

**Proof.** See proof of Proposition 38.
An $O(n^8)$ Algorithm

There is an optimal Parallel-Dominant schedule and it comes directly from the definition of $P_k(t_l, t_r, \mu_r)$ that the optimum is met for

\[
\begin{align*}
  k &:= n \\
  t_l &:= \min(\Theta) - p \\
  t_r &:= \max(\Theta) + p \\
  \mu_r &:= 0
\end{align*}
\]

Thanks to Proposition 39, we have a straight dynamic programming algorithm to reach the optimum. The relevant values for $t_l$ and $t_r$ are those in $\Theta$ plus the special values $\min(\Theta) - p$ and $\max(\Theta) + p$. The relevant values for $k$ and $\mu_r$ are in $\{0, \ldots, n\}$. The values of $P_k(t_l, t_r, \mu_r)$ are stored in a multi-dimensional array of size $O(n^8)$.

In the initialization phase, $P_0(t_l, t_r, \mu_r)$ is set to 0 if $t_l + p \leq t_r$ and to a very large value otherwise. It runs in $O(n^5)$. We then iterate on all possible values of the parameters to reach the optimum (cf. Algorithm 6). For each value of the parameters, a minimum over $t$ ($O(n^2)$ terms) is computed. This leads to an overall time complexity of $O(n^8)$. A rough analysis of the space complexity leads to an $O(n^8)$ bound but, as for the serial problem, the algorithm can be implemented with 2 arrays of $O(n^5)$ size.

Bar-Noy, Guha, Katz, Naor, Schieber and Shachnai [28] have proposed an $O(nF^2 + 3F + 2 \log n)$ dynamic programming algorithm for the more general case where $F$ families of jobs, all jobs in the same family having identical processing times, have to be batched on a parallel batching machine. This improves on the result presented above.

5.2.4 Open Questions

We have shown that with arbitrary release dates and identical processing times, (1) the unbounded parallel problem is solvable in polynomial time for any regular objective function, (2) the parallel and the serial problems are also solvable in polynomial time for any ordered objective function. As shown in Chapter 2, $\sum w_i U_i$, $\sum w_i C_i$ or $\sum T_i$ are ordered objective functions or can be transformed into ordered objective functions. Hence, we have shown that the problems

- $1|s\text{-}batch, r_i, p_i = p| \sum w_i U_i,$
- $1|s\text{-}batch, r_i, p_i = p| \sum w_i C_i,$
- $1|s\text{-batch}, r_i, p_i = p| \sum T_i$,
- $1|p\text{-batch}, b < n, r_i, p_i = p| \sum w_i U_i$,
- $1|p\text{-batch}, b < n, r_i, p_i = p| \sum w_i C_i$,
- $1|p\text{-batch}, b < n, r_i, p_i = p| \sum T_i$,
- $1|p\text{-batch}, r_i, p_i = p| \sum w_i T_i$,

are solvable in polynomial time by dynamic programming. To conclude we would like to point out that, for the criteria $\sum w_i T_i$, the complexity of batching identical jobs on a serial or on a parallel bounded machine is still an open question.
Batching Equal Length Jobs
Chapter 6

Conclusion

In this first part, we have provided a set of techniques to solve a large variety of equal-processing-time scheduling problems. Most of the problems studied were open before and we believe that our algorithms contribute to a better understanding, as far as scheduling is concerned, of the borderline between NP-Hard and polynomial problems. Although we have tried to be very exhaustive, there are still many “simple” open equal-execution time scheduling problems.

When there are no precedence constraints, a very challenging problem is $1|p_i = p, r_i|\sum w_i T_i$. It seems that our dynamic programming techniques cannot be extended to this case. Indeed, to decompose the problem, we always try to find the “less urgent” job in the instance. It is easy to see that for $\sum w_i C_i$, the less urgent job is the one with minimal weight and for $\sum T_i$, it is the one with largest due-date. The main issue with the weighted tardiness criteria is that a job with a very large due-date can also have a very large weight. Hence, it seems difficult to generalize this notion of “less urgent” job.

Many preemptive equal-execution-time problems are also open according to the Brucker and Knust complexity list [47]. Although the corresponding results are not described in this manuscript, we have shown recently that, for several problems, preemption is redundant. This allows us to close a preemptive problem when there is a polynomial solution of its non-preemptive counterpart. Together with Timkovsky [26] we have shown that preemption is redundant for $P2|\text{pmtn, outtree}, r_j, p_j = 1|\sum C_j$ (and thus the problem can be solved in polynomial time with Hu’s algorithm). Brucker, Hurink and Knust have extended this result to an arbitrary number of machines [42]. At the same time, we have shown with Timkovsky that preemption is also redundant for an arbitrary precedence graph on a single machine ($1|\text{pmtn, prec, } r_j, p_j = p|\sum C_j$). More recently, Brucker, Heitmann and Hurink [40] have shown that preemption is redundant for $P|\text{pmtn, } p_j = 1|\sum T_j$. We believe that all these existing results (and more) can be presented in a common generic framework. Preemption redundancy is, we think, a very promising research direction.

Finally, we would like to mention some negative results on the parallel unit execution time problems with precedence constraints. $P3|\text{prec}|C_{\text{max}}$, one of the most challenging problem in the history of scheduling, is still open. Despite our efforts, it seems that none of the techniques described in this manuscript can be, a priori generalized to handle arbitrary precedence constraints.
Conclusion
Part II

Constraint-Based Scheduling
Chapter 7

Introduction

Constraint-Based Scheduling can be defined as the discipline that studies how to solve scheduling problems by using Constraint Programming (CP). In this introduction we first pay attention to the basics of CP, after which we introduce the scheduling problems that are considered.

7.1 Constraint Programming

Constraint Programming is a paradigm aimed at solving combinatorial optimization problems. Often these combinatorial optimization problems are solved by defining them as one or several instances of the Constraint Satisfaction Problem (CSP). Informally speaking, an instance of the CSP is described by a set of variables, a set of possible values for each variable, and a set of constraints between the variables. The set of possible values of a variable is called the variable’s domain. A constraint between variables expresses which combinations of values for the variables are allowed. Constraints can be stated either explicitly (also called extensionally), e.g., an arithmetic formula, or implicitly (also called intentionally), where each constraint is expressed as a set of tuples of values that satisfy the constraint. An example of an implicitly stated constraint on the integer variables $x$ and $y$ is $x < y$. An example of an explicitly stated constraint on the integer variables $x$ and $y$ with domains $\{1, 2, 3\}$ and $\{1, 2, 3, 4\}$ is the tuple set $\{(1, 1), (2, 3), (3, 4)\}$. The question to be answered for an instance of the CSP is whether there exists an assignment of values to variables, such that all constraints are satisfied. Such an assignment is called a solution of the CSP.

One of the key ideas of CP is that constraints can be used “actively” to reduce the computational effort needed to solve combinatorial problems. Constraints are thus not only used to test the validity of a solution, as in conventional programming languages, but also in an active mode to remove values from the domains, deduce new constraints, and detect inconsistencies. This process of actively using constraints to come to certain deductions is called constraint propagation. The specific deductions that result in the removal of values from the domains are called domain reductions. The set of values in the domain of a variable that are not invalidated by constraint propagation is called the current domain of that variable. As an example of the benefit of the active use of constraints, let us look at the combination of the three constraints $y > x$, $x > 8$, and $y \leq 9$ on the integer variables $x$ and $y$. Looking at the first two constraints, we can deduce that the value of $y$ is greater than 9. This is administered in the current domain of $y$. Then by using the constraint $y \leq 9$, obviously a contradiction can be detected. Without constraint propagation, the “$y \leq 9$” test could not be performed before the instantiation of $y$ and thus no contradiction would be detected. The current domains of the variables play a central role in constraint propagation as a basic means of communication between constraints. In this small example the fact the current domain of $y$ only includes values greater than 9 makes it trivial for the constraint $y \leq 9$ to detect a contradiction.

As the general CSP is NP-complete [108], constraint propagation is usually incomplete. This means that some but not all the consequences of the set of constraints are deduced. In particular, constraint propagation cannot detect all inconsistencies. Consequently, one needs to perform some kind of search to determine if the CSP instance at hand has a solution or not. Most commonly,
search is performed by means of a tree search algorithm. The two main components of a tree search algorithm are (i) the way to go “forward”, \textit{i.e.}, the definition of which decisions are taken at which point in the search, and (ii) the way to go “backward”, \textit{i.e.}, the definition of the backtracking strategy which states how the algorithm shall behave when a contradiction is detected. The description of which decisions to take at which point in the search is often referred to as the \textit{search heuristic}. In general, the decisions that are taken correspond to adding additional constraints. As such during search the constraint propagation reasons on the combination of the original constraints and the constraints coming from the decisions taken. When a contradiction is detected it thus means it is proven that there is no feasible assignment of values to variables given the original data of the CSP and the heuristic decisions that have been made. The most commonly used backtracking strategy is depth first chronological backtracking, \textit{i.e.}, the last decision is undone and an alternative constraint is imposed. More complex backtracking strategies can be found for example in [140, 52, 188]. In Section 12.3.4 we present an application where depth first chronological backtracking is compared to alternatives such as limited discrepancy search [116].

![Figure 7.1: The behavior of a Constraint Programming system.](image)

The overall behavior of a CP system is depicted in Figure 7.1. This figure underlines the fact that \textit{problem definition}, \textit{constraint propagation}, and the \textit{search heuristic} and \textit{backtracking strategy} are clearly separated. This separation is based upon the following fundamental principles of CP that became precise in the late 1970’s and early 1980’s. In [206] the separation between deductive methods generating additional constraints from existing constraints, and search algorithms used to systematically explore the solution space is advocated. For CP the deductive method is constraint propagation. The distinction between the logical representation of constraints and the control of their use is in accordance with the equation stated by Kowalski for logic programming: \textit{Algorithm = Logic + Control} [132]. Another important principle used in CP is the so-called “locality principle”, which states that each constraint must propagate as locally as possible, independently of the existence or the non-existence of other constraints [207].

When defining the problem in terms of variables and constraints, in practice the user of a CP tool is offered an array of pre-defined constraints (\textit{e.g.}, constraints on integers, constraints on sets, scheduling constraints) with corresponding propagation algorithms. The locality principle is of crucial importance for the practical use of the pre-defined constraints as it implies that the constraint propagation algorithms can be reused in all applications where similar constraints apply. On top of this many CP tools offer ways to define new constraints with corresponding propagation algorithms that then seamlessly can be used in cooperation with the pre-defined constraints. CP tools also offer support to specify the search heuristic and the backtracking strategy. Again pre-defined heuristics
that the original constraints plus the decisions are inconsistent. This deduction is made before the last decision taken, in Step 3, and try an alternative choice, in Step 3’. Constraint propagation thus continues and founds that the current domain of all variables are assigned a value, again an example how search effort is reduced by constraint variables. In Step 3 (cont.) two effects take place. The constraint propagation leaves only one propagation.

Although this problem is of little practical importance it does show that the combination of the model, the search heuristic, the constraint propagation, and the backtracking strategy defines the performance of a CP algorithm. As such if one wants to improve the performance of a CP approach, one needs to work on at least one of these components. We remark that in CP improving the model often is aimed at being able to define a better search heuristic or to have better (pre-dened) constraint propagation.

As already mentioned a crucial component in a CP approach is the constraint propagation. Several techniques have been developed to do constraint propagation. Among these techniques, let
Figure 7.2: Solving the 6-queens problem.
us mention arc-consistency.

**Definition 27.** Given a constraint \( c \) over \( n \) variables \( x_1, \ldots, x_n \) and a domain \( d(x_i) \) for each variable \( x_i \), \( c \) is said to be “arc-consistent” if and only if for any variable \( x_i \) and any value \( v_i \in d(x_i) \), there exist values \( v_1, \ldots, v_{i-1}, v_{i+1}, \ldots, v_n \) in \( d(x_1), \ldots, d(x_{i-1}), d(x_{i+1}), \ldots, d(x_n) \) such that \( c(v_1, \ldots, v_n) \) holds.

A huge amount of work has been carried out on constraint propagation algorithms that maintain arc-consistency on the constraints of a binary CSP, i.e., of a CSP whose constraints link at most two variables [169, 161, 167, 119, 33]. Numeric CSPs are special cases of the CSP where the variables are constrained to take numeric values. For numeric CSPs the domain of a variable \( x \) often is represented by only its smallest value \( lb(x) \) and its largest value \( ub(x) \), i.e., by the interval \([lb(x), ub(x)]\). This compact representation is especially useful to tackle real-life problems for which explicitly maintaining the set of values that can be taken by each variable throughout the search tree may not be reasonable. A usual way to propagate constraints on such variables is to achieve arc-B-consistency [155], i.e., arc-consistency restricted to the bounds of the domains. Arc-B-consistency can be easily achieved on some arithmetic constraints such as linear constraints [155].

**Definition 28.** Given a constraint \( c \) over \( n \) variables \( x_1, \ldots, x_n \) and a domain \( d(x_i) = [lb(x_i), ub(x_i)] \) for each variable \( x_i \), \( c \) is said to be “arc-B-consistent” if and only if for any variable \( x_i \) and each of the bound values \( v_i = lb(x_i) \) and \( v_i = ub(x_i) \), there exist values \( v_1, \ldots, v_{i-1}, v_{i+1}, \ldots, v_n \) in \( d(x_1), \ldots, d(x_{i-1}), d(x_{i+1}), \ldots, d(x_n) \) such that \( c(v_1, \ldots, v_n) \) holds.

In the following, maintaining arc-consistency (or arc-B-consistency) on a constraint means that the domains (respectively the bounds) of the variables involved in the constraint are maintained to ensure that the constraint is arc-consistent (resp. arc-B-consistent).

**Example 1.** Maintaining arc-consistency or arc-B-consistency on

\[
\sum_{i=1}^{n} \lambda_i x_i \leq \Lambda \tag{7.1}
\]

where \( \lambda_1, \ldots, \lambda_n \) and \( \Lambda \) are non negative values. It is easy to see that (7.1) leads to:

\[
\forall i, x_i \leq \frac{\Lambda - \sum_{j \neq i} \lambda_j x_j}{\lambda_i}
\]

Consequently, the upper bound of \( x_i \) can be adjusted to

\[
\frac{\Lambda - \sum_{j \neq i} \lambda_j lb(x_j)}{\lambda_i}
\]

This upper bound needs to be recomputed only when the lower bound of one of the variables \( x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n \) is modified.

**Example 2.** Maintaining arc-consistency or arc-B-consistency on the disjunctive constraint \([x_1 = 0] \lor [x_2 = 0]\). As soon as the value 0 is removed from the domain of \( x_1 \) (resp. of \( x_2 \)) then the second (resp. first) disjunct is imposed, i.e., \( x_2 = 0 \) (resp. \( x_1 = 0 \)).

**Example 3.** Maintaining arc-consistency on \( x_1 \neq x_2 \). When \( x_1 \) is bound to \( v_1 \), this value is removed from the domain of \( x_2 \) (and conversely). Notice that in this example, arc-B-consistency and arc-consistency differ. Indeed, when only arc-B-consistency is maintained, \( v_1 \) is removed from \( d(x_2) \) only if it is equal to either \( lb(x_2) \) or \( ub(x_2) \).

In the past few years much evidence was gathered that the use of “global” constraint propagation algorithms can drastically enhance the efficiency of CP systems. Such algorithms are able to take into account a set of constraints from a global point of view, and can propagate them very efficiently.

Let us consider for instance the so-called “all-different” constraint. It constrains a set of \( n \) variables to take pairwise distinct values. Such a constraint can obviously be propagated by maintaining
arc-consistency on \( n(n - 1)/2 \) “local” constraints that state for any pair of variables \( x \) and \( y \) that \( x \neq y \). An algorithm to achieve the consistency of the global “all-different” constraint is described in [191]. The constraint is modeled by a bi-partite graph. One of the sets of vertices is the set of the variables while the other one is the union of the domains. An edge between a variable and a value states that the given value is in the domain of the given variable. The constraint is consistent if and only if there is a matching whose cardinality is \( n \). An algorithm is devised to ensure the arc-consistency of the global constraint. The domains of the variables are filtered to remove all the values that would make the constraint inconsistent. Another famous global constraint is the resource constraint that states that a set of activities cannot overlap in time (this constraint will be presented in detail in Chapter 8).

One of the key factors of the recent successes of Constraint-Based Scheduling lies in the fact that a combination was found of the best of two fields of research that pay attention to scheduling, namely Operations Research (OR) and Artificial Intelligence (AI).

Traditionally, a lot of the attention in OR has been paid to rather “pure” scheduling problems that are based on relatively simple mathematical models (cf., First Part of this manuscript). For solving the problem at hand, the combinatorial structure of the problem is heavily exploited, leading to improved performance characteristics. We could say that an OR approach often aims at achieving a high level of efficiency in its algorithms. However, when modeling a practical scheduling problem using these classical models, one is often forced to discard degrees of freedom and side constraints that exist in the practical scheduling situation. Discarding degrees of freedom may result in the elimination of interesting solutions, regardless of the solution method used. Discarding side constraints gives a simplified problem and solving this simplified problem may result in impractical solutions for the original problem. In contrast, AI research tends to investigate more general scheduling models and tries to solve the problems by using general problem-solving paradigms. We could say an AI approach tends to focus more on the generality of application of its algorithms. This, however, implies that AI algorithms may perform poorly on specific cases, compared to OR algorithms.

So, on the one hand we have OR which offers us efficient algorithms to solve problems that in comparison have a more limited application area. On the other hand we have AI that offers us algorithms that are more generally applicable, but that might suffer from somewhat poor performance in the specific cases an efficient OR algorithm exists. An important way to combine the two was found by incorporating OR algorithms inside global constraints. Examples thereof are the already mentioned all-different constraint and the resource constraint on a single machine. The basics of many of the algorithms inside global constraints, certainly in the early stages of the field, can be found in OR. By applying the locality principle, such specialized algorithms can work side by side with general propagation algorithms that take care of the rest of the constraints, the side constraints, etc. In this way one can preserve the general modeling and problem-solving paradigm of CP while the integration of efficient propagation algorithms improves the overall performance of the approach. Stated in another way, efficient OR algorithms integrated in a CP tool allow the user to benefit from the efficiency of OR techniques in a flexible framework. All this said, we want to remark that over the years the distinction between AI and OR is often becoming less and less clear and is also deemed less and less important.

### 7.2 A Constraint-Based Scheduling Model

When looking at the type of resources found in a problem, we distinguish disjunctive scheduling and cumulative scheduling. In a disjunctive scheduling problem, all resources are machines and thus can execute at most one activity at a time. In a cumulative scheduling problem, resources exist that can execute several activities in parallel, of course provided that the resource capacity is not exceeded.

When looking at the type of activities in a problem, we distinguish non-preemptive scheduling, preemptive scheduling, and elastic scheduling. In non-preemptive scheduling, activities cannot be interrupted. Each activity must execute without interruption from its start time to its end time. In preemptive scheduling, activities can be interrupted at any time, e.g., to let some other activities execute. In elastic scheduling the amount of resource assigned to an activity \( A_i \) can, at any time
t, assume any value between 0 and the resource capacity, provided that the sum over time of the assigned capacity equals a given value called energy. The equivalent notion of energy in the case of a non-preemptive activity is the product of its processing time and the capacity required.

We furthermore distinguish decision problems and optimization problems. In decision problems, one has only to determine whether a schedule exists that meets all constraints. In optimization problems, an objective function has to be minimized. Although the minimization of the makespan, i.e., the end time of the schedule, is commonly used, other criteria are sometimes of great practical interest (e.g., the number of activities performed with given delays, the maximal or average tardiness or earliness, the peak or average resource utilization, the sum of setup times or costs).

### 7.2.1 Activities

A non-preemptive scheduling problem can be efficiently encoded as a CSP in the following way. For each activity three variables are introduced, \(\text{start}(A_i)\), \(\text{end}(A_i)\), and \(\text{proc}(A_i)\). They represent the start time, the end time, and the processing time of \(A_i\), respectively.

With \(r_i\) the release date and \(d_i\) the deadline of activity \(A_i\) as defined in the initial data of the scheduling problem, \([r_i, d_i]\) is the time window in which \(A_i\) has to execute. Based on that the initial domains of \(\text{start}(A_i)\) and \(\text{end}(A_i)\) are \([r_i, \text{lst}_i]\) and \([\text{eet}_i, d_i]\), respectively. Here \(\text{lst}_i\) and \(\text{eet}_i\) stand for the latest start time and the earliest end time of \(A_i\). For convenience, we also use this notation to denote the current domains of \(\text{start}(A_i)\) and \(\text{end}(A_i)\), i.e., the domains when we are in the process of propagating constraints. Of course in that case instead of the initial release date and deadline, \(r_i\) and \(d_i\) denote the current earliest start time and latest end time.

The processing time of the activity is defined as the difference between the end time and the start time of the activity: \(\text{proc}(A_i) = \text{end}(A_i) - \text{start}(A_i)\). \(p_i\) denotes the smallest value in the domain of \(\text{proc}(A_i)\). All data related to an activity are summarized in Figure 7.3. Light gray is used to depict the time-window \([r_i, d_i]\) of an activity and dark gray is used to represent the processing time of the activity.

![Figure 7.3: Data related to an activity](image)

Preemptive scheduling problems are more difficult to represent since a schedule is more complex than a simple set of starting times of activities. We discuss two possibilities. One can either associate a set variable (i.e., a variable the value of which will be a set) \(\text{set}(A_i)\) with each activity \(A_i\), or alternatively define a 0-1 variable \(X(A_i, t)\) for each activity \(A_i\) and time \(t\). \(\text{set}(A_i)\) represents the set of times at which \(A_i\) executes, while \(X(A_i, t)\) takes value 1 if and only if \(A_i\) executes at time \(t\). The processing time \(\text{proc}(A_i)\) of \(A_i\) is defined as the number of time points \(t\) at which \(A_i\) executes, i.e., as \(|\text{set}(A_i)|\). In practice, the \(X(A_i, t)\) variables are not represented explicitly as the value of \(X(A_i, t)\) is 1 if and only if \(t\) belongs to \(\text{set}(A_i)\).

Assuming time is discretized, \(\text{start}(A_i)\) and \(\text{end}(A_i)\) can be defined by \(\text{start}(A_i) = \min_{t \in \text{set}(A_i)} t\) and \(\text{end}(A_i) = \max_{t \in \text{set}(A_i)} t + 1\). Notice that in the non-preemptive case, \(\text{set}(A_i) = [\text{start}(A_i), \text{end}(A_i)]\), with the interval \([\text{start}(A_i), \text{end}(A_i)]\) closed on the left and open on the right so that \(|\text{set}(A_i)| = \text{end}(A_i) - \text{start}(A_i) = \text{proc}(A_i)\).
These constraints are easily propagated by maintaining a lower bound and an upper bound for the set variable \( \text{set}(A_i) \). The lower bound \( \text{lb}(\text{set}(A_i)) \) is a series of disjoint intervals \( ILB^i \) such that each \( ILB^i \) is constrained to be included in \( \text{set}(A_i) \). The upper bound \( \text{ub}(\text{set}(A_i)) \) is a series of disjoint intervals \( IUB^i \) such that \( \text{set}(A_i) \) is constrained to be included in the union of the \( IUB^i \). If the size of the lower bound (i.e., the sum of the sizes of the \( ILB^i \)) becomes larger than the upper bound of \( \text{proc}(A_i) \) or if the size of the upper bound (i.e., the sum of the sizes of the \( IUB^i \)) becomes smaller than lower bound of \( \text{proc}(A_i) \), a contradiction is detected. If the size of the lower bound (or of the upper bound) becomes equal to the upper bound (respectively, lower bound) of \( \text{proc}(A_i) \), \( \text{set}(A_i) \) receives the lower bound (respectively, the upper bound) as its final value. Minimal and maximal values of \( \text{start}(A_i) \) and \( \text{end}(A_i) \), i.e., earliest and latest start and end times, are also maintained. Each of the following rules, considered independently one from another, is used to update the bounds of \( \text{set}(A_i) \), \( \text{start}(A_i) \) and \( \text{end}(A_i) \). Let \( t \) be any point in time, then

\[
t < r_i \Rightarrow t \notin \text{set}(A_i)
\]
\[
t \in \text{lb}(\text{set}(A_i)) \Rightarrow \text{start}(A_i) \leq t
\]
\[
\bar{a}_i \leq t \Rightarrow t \notin \text{set}(A_i)
\]
\[
t \in \text{lb}(\text{set}(A_i)) \Rightarrow t < \text{end}(A_i)
\]
\[
[\forall u < t, u \notin \text{ub}(\text{set}(A_i))] \Rightarrow t \leq \text{start}(A_i)
\]
\[
[\forall u > t, u \notin \text{ub}(\text{set}(A_i))] \Rightarrow \text{end}(A_i) \leq t
\]
\[
\text{start}(A_i) \leq \max\{u : \exists S \subseteq \text{ub}(\text{set}(A_i)), |S| = p_i \land \min(S) = u\}
\]
\[
\text{end}(A_i) \geq \min\{u : \exists S \subseteq \text{ub}(\text{set}(A_i)), |S| = p_i \land \max(S) = u - 1\}
\]

Needless to say, whenever any of these rules leads to a situation where the lower bound of a variable is larger than its upper bound, a contradiction is detected.

In the following, we may occasionally use the notations \( X(A_i, t) \) and \( \text{set}(A_i) \) for an activity \( A_i \) that cannot be interrupted. In such a case, the following rules are also applied:

\[
X(A_i, t) = 0 \land t < \text{eet}_i \Rightarrow \text{start}(A_i) > t
\]
\[
X(A_i, t) = 0 \land \text{lst}_i \leq t \Rightarrow \text{end}(A_i) \leq t
\]

### 7.2.2 Temporal Relations

Temporal relations between activities can be expressed by linear constraints between the start and end variables of activities. For instance, a precedence between two activities \( A_i \) and \( A_j \) is modeled by the linear constraint \( \text{end}(A_i) \leq \text{start}(A_j) \). Such constraints can be easily propagated using a standard arc-B-consistency algorithm [155]. In addition, a variant of Ford’s algorithm (see for instance [111]) proposed by Cesta and Oddi [72] can be used to detect any inconsistency between such constraints, in time polynomial in the number of constraints (and independent of the domain sizes).

### 7.2.3 Resource Constraints

Resource constraints represent the fact that activities require some amount of resource throughout their execution. Given an activity \( A_i \) and a resource \( R \) whose capacity is \( \text{cap}(R) \), let \( \text{cap}(A_i, R) \) be the variable that represents the amount of resource \( R \) required by activity \( A_i \). For fully elastic activities, the \( \text{cap}(A_i, R) \) variable is not meaningful and we need to introduce a variable \( E(A_i, R) \) that represents the energy required by the activity on the resource \( R \). Note that for non-elastic activities, we have \( E(A_i, R) = \text{cap}(A_i, R) \text{proc}(A_i) \). To represent a schedule, we need a variable \( E(A_i, t, R) \) that denotes the number of units of the resource \( R \) used by activity \( A_i \) at time \( t \). In all cases, we have the constraint stating that enough resource must be allocated to activities to cover the energy requirement:

\[
E(A_i, R) = \sum_t E(A_i, t, R)
\]
If $A_i$ is not an elastic activity, there are some strong relations between $E(A_i, t, R)$ and $X(A_i, t)$:

$$E(A_i, t, R) = X(A_i, t) \cdot cap(A_i, R)$$

For elastic activities, we have a weaker relation between the variables:

$$[E(A_i, t, R) > 0] \Leftrightarrow [X(A_i, t) > 0]$$

Generally speaking, the resource constraint can be written as follows. For each point in time $t$

$$\sum_{i=1}^{n} E(A_i, t, R) \leq cap(R) \quad (7.2)$$

Depending on the scheduling situation, (7.2) can be rewritten. In the non-preemptive case, (7.2) leads for all times $t$ to

$$\sum_{A_i: \text{start}(A_i) \leq t \leq \text{end}(A_i)} cap(A_i, R) \leq cap(R) \quad (7.3)$$

In the preemptive case, (7.2) leads for all times $t$ to

$$\sum_{A_i: \text{start}(A_i) \leq t \leq \text{end}(A_i)} X(A_i, t) \cdot cap(A_i, R) \leq cap(R) \quad (7.4)$$

In the following, $c_{i,R}$ and $e_{i,R}$ denote the minimal capacity and energy required by the activity $A_i$ from resource $R$. Finally, $C_R$ denotes the maximal value in the domain of the resource capacity variable. Sometimes, if no confusion is possible “$R$” is omitted, leading to $c_i$, $e_i$, and $C$, respectively.

### 7.2.4 Extensions of the Model

Although the model presented until now covers quite a number of real-life problems, we want to include two extensions that are frequently found in industrial applications, namely alternative resources and transition times and transition costs. We refer to Chapter 15 for a discussion on other extensions found in industry.

#### Alternative Resources

In some scheduling situations an activity $A_i$ can be scheduled on any one resource from a set $S$ of resources. We say that $S$ is the set of alternative resources for $A_i$. For each set of alternative resources a variable $altern(A_i)$ is introduced. To simplify notation, we assume that resources are numbered from 1 to $m$ and that $altern(A_i)$ denotes the variable whose value represents the index of the resource on which $A_i$ is executed. We remark that quite commonly the processing time of the activity depends on the resource on which the given activity is executed, i.e., the resources are unrelated. Another commonly found type of constraints reasons on interdependencies of resource allocations, e.g., a constraint like “if $A_1$ is scheduled on resource $R_1$ then $A_3$ has to be scheduled on resource $R_2$”.

Alternative resource constraints are propagated as if $A_i$ were split into $|domain(altern(A_i))|$ fictive activities $A_i^u$ where each activity $A_i^u$ requires resource $R_u$ [153]. Following this notation $r_i^u$ denotes the earliest start time of $A_i^u$, etc. The alternative resource constraint maintains the constructive disjunction between the alternative activities $A_i^u$ for $u \in domain(altern(A_i))$, i.e., it ensures that:

\[
\begin{align*}
    r_i &= \min\{r_i^u : u \in domain(altern(A_i))\} \\
    lst_i &= \max\{lst_i^u : u \in domain(altern(A_i))\} \\
    eet_i &= \min\{eet_i^u : u \in domain(altern(A_i))\} \\
    d_i &= \max\{d_i^u : u \in domain(altern(A_i))\} \\
    lb(proc(A_i)) &= \min\{lb(proc(A_i^u)) : u \in domain(altern(A_i))\} \\
    ub(proc(A_i)) &= \max\{ub(proc(A_i^u)) : u \in domain(altern(A_i))\}
\end{align*}
\]
Constraint propagation will deduce new bounds for alternative activities $A^u_i$ on the alternative resource $R_u$. Whenever the bounds of an activity $A^u_i$ turn out to be incoherent, the resource $R_u$ is simply removed from the set of possible alternative resources for activity $A_i$, i.e., $\text{domain}(\text{altern}(A_i))$ becomes $\text{domain}(\text{altern}(A_i)) - \{u\}$.

### Transition Times and Transition Costs

Allahverdi, Gupta, and Aldowaisan, in reviewing the research on scheduling involving setup considerations [7], discuss the importance of scheduling with sequence dependent setups in real-life applications also formed the basis for the motivation for considering setup times and setup costs with attention.

The setup time (transition time) between two activities $A_1$ and $A_2$ is defined as the amount of time $\text{setup}(A_1, A_2)$ that must elapse between the end of $A_1$ and the start of $A_2$, when $A_1$ precedes $A_2$. A setup cost $\text{setupCost}(A_1, A_2)$ can also be associated to the transition between $A_1$ and $A_2$. The objective of the scheduling problem can be to find a schedule that minimizes the sum of the setup costs.

Throughout the manuscript, we consider that activities subjected to setups are to be scheduled on the same machine (the semantics of setups is much more complex on resources of capacity greater than 1). However, setup considerations can be combined with alternative resources. In such a case, we have to consider that two parameters are associated to each tuple $(A_i, A_j, M_u)$: the setup time $\text{setup}(A_i, A_j, M_u)$ and the setup cost $\text{setupCost}(A_i, A_j, M_u)$ between activities $A_i$ and $A_j$ if $A_i$ and $A_j$ are scheduled sequentially on the same machine $M_u$. In such a case, $\text{start}(A^u_i) \geq \text{end}(A_i) + \text{setup}(A_i, A_j, M_u)$. There may furthermore exist a setup time $\text{setup}(-, A_i, M_u)$ (with corresponding cost $\text{setupCost}(-, A_i, M_u)$) that has to elapse before the start of $A_i$, when $A_i$ is the first activity on $M_u$ and, similarly, a teardown time $\text{setup}(A_i, -, M_u)$ (with corresponding cost $\text{setupCost}(A_i, -, M_u)$) that has to elapse after the end of $A_i$ when $A_i$ is the last activity on $M_u$.

#### 7.2.5 Objective Function

To model the objective function, we add a variable $\text{criterion}$ to the model. It is constrained to equal the value of the objective function. For most problems the objective function is a function of the end variables of the activities.

$$\text{criterion} = F(\text{end}(A_1), \ldots, \text{end}(A_n)) \quad (7.5)$$

Once all constraints of the problem are added, a common technique to look for an optimal solution is to solve successive decision variants of the problem. Several strategies can be considered to minimize the value of $\text{criterion}$. One way is to iterate on the possible values, either from the lower bound of its domain up to the upper bound until one solution is found, or from the upper bound down to the lower bound determining each time whether there still is a solution. Another way is to use a dichotomizing algorithm, where one starts by computing an initial upper bound $ub(\text{criterion})$ and an initial lower bound $lb(\text{criterion})$ for $\text{criterion}$. Then

1. Set $D = \left\lfloor \frac{lb(\text{criterion}) + ub(\text{criterion})}{2} \right\rfloor$

2. Constrain $\text{criterion}$ to be at most $D$. Then solve the resulting CSP, i.e., determine a solution with $\text{criterion} \leq D$ or prove that no such solution exists. If a solution is found, set $ub(\text{criterion})$ to the value of $\text{criterion}$ in the solution; otherwise, set $lb(\text{criterion})$ to $D + 1$.

3. Iterate steps 1 and 2 until $ub(\text{criterion}) = lb(\text{criterion})$.

Specific propagation techniques are used to propagate resource constraints (7.2), (7.3) or (7.4). Several sections of this manuscript are dedicated to these techniques. The objective constraint (7.5) is most often a simple arithmetic expression on which arc-B-consistency can be easily achieved.
Considering the objective constraint and the resource constraints independently is not a problem when \( F \) is a “maximum” such as \( C_{\text{max}} \) or \( T_{\text{max}} \). Indeed, the upper bound on criterion is directly propagated on the completion time of each activity, i.e., latest end times are tightened efficiently. The situation is much more complex for sum functions such as \( \sum w_i C_i \), \( \sum w_i T_i \), or \( \sum w_i U_i \). For these functions, efficient constraint propagation techniques must take into account the resource constraints and the objective constraint simultaneously. We pay attention to this in Chapters 11 and 14.
Chapter 8

Propagation of the One-Machine Resource Constraint

In this chapter we study several methods to propagate a One-Machine resource constraint: A set of \( n \) activities \( \{A_1, \ldots, A_n\} \) require the same resource of capacity 1. The propagation of resource constraints is a purely deductive process that allows to deduce inconsistencies and to tighten the temporal characteristics of activities and resources. In the non-preemptive case (Section 8.1), the earliest start times and the latest end times of activities are updated. When preemption is allowed (Section 8.2), modifications of earliest end times and latest start times also apply.

8.1 Non-Preemptive Problems

First we consider the simple Time-Table mechanism, widely used in Constraint-Based Scheduling tools, that allows to propagate the resource constraint in an incremental fashion. We then consider a disjunctive formulation of the One-Machine resource constraint that compares the temporal characteristics of pairs of activities. In Section 8.1.3, we describe the Edge-Finding propagation technique, which is extremely efficient for solving disjunctive scheduling problems like the Job-Shop. In Section 8.1.4, we present a mechanism, known as “Not-First, Not-Last”, that extends the basic Edge-Finding mechanism and allows additional deductions. Finally, some extensions of these mechanisms are presented in Section 8.1.5.

8.1.1 Time-Table Constraint

A simple mechanism to propagate resource constraints in the non-preemptive case relies on an explicit data structure called “Time-Table” to maintain information about resource utilization and resource availability over time. Resource constraints are propagated in two directions: from resources to activities, to update the time bounds of activities (earliest start times and latest end times) according to the availability of resources; and from activities to resources, to update the Time-Tables according to the time bounds of activities. Although several variants exist [148, 106, 149, 202, 157] the propagation mainly consists of maintaining for any time \( t \) arc-B-consistency on the formula:

\[
\sum_{i=1}^{n} E(A_i, t) \leq 1
\]

Since \( E(A_i, t) = X(A_i, t) \) and since \( X(A_i, t) \) equals 1 if and only if \( \text{start}(A_i) \leq t < \text{end}(A_i) \), this leads in turn to some adjustments of \( r_i, eet_i, lst_i \) and \( d_i \):
\[\text{start}(A_i) \geq \min\{t : \text{ub}(X(A_i, t)) = 1\}\]
\[\text{end}(A_i) \leq \max\{t : \text{ub}(X(A_i, t)) = 1\} + 1\]
\[X(A_i, t) = 0 \land [t < \text{eet}_i] \Rightarrow [\text{start}(A_i) > t]\]
\[X(A_i, t) = 0 \land [\text{lst}_i \leq t] \Rightarrow [\text{end}(A_i) \leq t]\]

| Before Propagation | \(r_i\) | \(d_i\) | \(p_i\)| | 0 | 1 | 2 | 3 | 4 | 5 |
|---------------------|--------|--------|--------|---|---|---|---|---|---|
| \(A_1\)            | 0      | 3      | 2      | | | | | | |
| \(A_2\)            | 0      | 4      | 2      | | | | | | |

| Propagation 1 | \(r_i\) | \(d_i\) | \(p_i\)| | 0 | 1 | 2 | 3 | 4 | 5 |
|---------------|--------|--------|--------|---|---|---|---|---|---|
| \(A_1\)      | 0      | 3      | 2      | | | | | | |
| \(A_2\)      | 2      | 4      | 2      | | | | | | |

| Propagation 2 | \(r_i\) | \(d_i\) | \(p_i\)| | 0 | 1 | 2 | 3 | 4 | 5 |
|---------------|--------|--------|--------|---|---|---|---|---|---|
| \(A_1\)      | 0      | 2      | 2      | | | | | | |
| \(A_2\)      | 2      | 4      | 2      | | | | | | |

Figure 8.1: Propagation of the Time-Table constraint.

Figure 8.1 displays two activities \(A_1\) and \(A_2\) which require the same resource of capacity 1. The latest start time \((\text{lst}_1 = d_1 - p_1 = 1)\) of \(A_1\) is smaller than its earliest end time \((\text{eet}_1 = r_1 + p_1 = 2)\). Hence, it is guaranteed that \(A_1\) will execute between 1 and 2. Over this period, \(X(A_1, t)\) is set to 1 and the corresponding resource amount is no longer available for \(A_2\). Since \(A_2\) cannot be interrupted and cannot be finished before 1, the earliest start and end times of \(A_2\) are updated to 2 and 4 (propagation 1). Then, \(X(A_2, t)\) is set to 1 over the interval \([2, 4]\), which results in a new propagation step, where the latest end time of \(A_1\) is set to 2 (propagation 2).

**8.1.2 Disjunctive Constraint Propagation**

In non-preemptive scheduling, two activities \(A_i\) and \(A_j\) requiring the same machine cannot overlap in time: either \(A_i\) precedes \(A_j\) or \(A_j\) precedes \(A_i\). If \(n\) activities require the resource, the constraint can be implemented as \(n(n-1)/2\) (explicit or implicit) disjunctive constraints. As for Time-Table constraints, variants exist in the literature \([96, 55, 98, 148, 203, 214, 20]\), but in most cases the propagation consists of maintaining arc-B-consistency on the formula:

\[[\text{end}(A_i) \leq \text{start}(A_j)] \lor [\text{end}(A_j) \leq \text{start}(A_i)]\]

Enforcing arc-B-consistency on this formula is done as follows: Whenever the earliest end time of \(A_i\) exceeds the latest start time of \(A_j\), \(A_i\) cannot precede \(A_j\); hence \(A_j\) must precede \(A_i\). The time bounds of \(A_i\) and \(A_j\) are consequently updated with respect to the new temporal constraint \(\text{end}(A_j) \leq \text{start}(A_i)\). Similarly, when the earliest possible end time of \(A_j\) exceeds the latest possible start time of \(A_i\), \(A_j\) cannot precede \(A_i\). When neither of the two activities can precede the other, a contradiction is detected. Disjunctive constraints provide more precise time bounds than the corresponding Time-Table constraints. Indeed, if an activity \(A_j\) is known to execute at some time \(t\) between the earliest start time \(r_i\) and the earliest end time \(\text{eet}_i\) of \(A_i\), then the first disjunct of the above formula is false. Thus, \(A_j\) must precede \(A_i\) and the propagation of the disjunctive constraint implies \(\text{start}(A_i) \geq \text{eet}_j > t\).
8.1 Non-Preemptive Problems

The earliest end time of each activity does not exceed its latest start time, so the Time-Table constraint cannot deduce anything. On the contrary, the propagation of the disjunctive constraint imposes \( \text{end}(A_1) \leq \text{start}(A_2) \) which, in turn, results in updating both \( \bar{d}_1 \) and \( r_2 \).

8.1.3 Edge-Finding

The term “Edge-Finding” denotes both a “branching” and a “bounding” technique \([8]\). The branching technique consists of ordering activities that require the same resource. At each node, a set of activities which are not finished at \( t \) is presented \([62]\). It consists of a “primal” algorithm to update earliest start times and a “dual” algorithm to update latest end times. The primal algorithm runs as follows:

- Compute Jackson’s Preemptive Schedule (JPS) for the resource under consideration. JPS is the preemptive schedule obtained by applying the following priority rule: whenever the resource is free and one activity is available, schedule the activity \( A_i \) for which \( d_i \) is the smallest. If an activity \( A_j \) becomes available while \( A_i \) is in process, stop \( A_i \) and start \( A_j \) if \( \bar{d}_j \) is strictly smaller than \( \bar{d}_i \); otherwise continue \( A_i \).
- For each activity \( A_i \), compute the set \( \Psi \) of the activities which are not finished at \( t = r_i \) on JPS. Let \( p_j^* \) be the residual processing time on the JPS of the activity \( A_j \) at time \( t \). Let \( \Psi_k = \{ A_j \in \Psi - \{ A_i \} : \bar{d}_j \leq \bar{d}_k \} \). Take the activities of \( \Psi \) in decreasing order of latest end times. The set \( \Psi \) is presented in \([62]\) and \([63, 67, 173, 51, 163, 180]\). The set \( \Psi \) is presented in \([62]\). It consists of the smallest of the earliest start times and latest end times of \( \Omega \). Finally, let \( p_\Omega \) be the sum of the minimal processing times of the activities in \( \Omega \). Let \( A_i \leq A_j \) \((A_i \gg A_j)\) mean that \( A_i \) executes before \((after)\) \( A_j \) and \( A_i \gg \Omega \) \((A_i \gg \Omega)\) mean that \( A_i \) executes before \((after)\) all the activities in \( \Omega \). Once again, variants exist \([185, 61, 62, 63, 67, 173, 51, 163, 180]\) but the following rules capture the “essence” of the Edge-Finding bounding technique:

\[
\begin{align*}
\forall \Omega, \forall A_i \notin \Omega, [\bar{d}_{\Omega \cup \{ A_i \}} - r_\Omega < p_\Omega + p_i] & \Rightarrow [A_i \ll \Omega] \quad (8.1) \\
\forall \Omega, \forall A_i \notin \Omega, [\bar{d}_{\Omega \cup \{ A_i \}} - r_\Omega < p_\Omega + p_i] & \Rightarrow [A_i \gg \Omega] \quad (8.2) \\
\forall \Omega, \forall A_i \notin \Omega, [A_i \ll \Omega] & \Rightarrow [\text{end}(A_i) \geq \min_{\emptyset \neq \Omega' \subseteq \Omega} (\bar{d}_{\Omega'} - p_{\Omega'})] \quad (8.3) \\
\forall \Omega, \forall A_i \notin \Omega, [A_i \gg \Omega] & \Rightarrow [\text{start}(A_i) \geq \max_{\emptyset \neq \Omega' \subseteq \Omega} (r_{\Omega'} + p_{\Omega'})] \quad (8.4)
\end{align*}
\]

If \( n \) activities require the resource, there are a priori \( O(n \times 2^n) \) pairs \((A_i, \Omega)\) to consider. An algorithm that performs all the time-bound adjustments in \( O(n^2) \) is presented in \([62]\). It consists of a “primal” algorithm to update earliest start times and a “dual” algorithm to update latest end times. The primal algorithm runs as follows:

- Compute Jackson’s Preemptive Schedule (JPS) for the resource under consideration. JPS is the preemptive schedule obtained by applying the following priority rule: whenever the resource is free and one activity is available, schedule the activity \( A_i \) for which \( \bar{d}_i \) is the smallest. If an activity \( A_j \) becomes available while \( A_i \) is in process, stop \( A_i \) and start \( A_j \) if \( \bar{d}_j \) is strictly smaller than \( \bar{d}_i \); otherwise continue \( A_i \).
- For each activity \( A_i \), compute the set \( \Psi \) of the activities which are not finished at \( t = r_i \) on JPS. Let \( p_j^* \) be the residual processing time on the JPS of the activity \( A_j \) at time \( t \). Let \( \Psi_k = \{ A_j \in \Psi - \{ A_i \} : \bar{d}_j \leq \bar{d}_k \} \). Take the activities of \( \Psi \) in decreasing order of latest end times. The set \( \Psi \) is presented in \([62]\) and \([63, 67, 173, 51, 163, 180]\). The set \( \Psi \) is presented in \([62]\) and \([63, 67, 173, 51, 163, 180]\). The set \( \Psi \) is presented in \([62]\) and \([63, 67, 173, 51, 163, 180]\). The set \( \Psi \) is presented in \([62]\) and \([63, 67, 173, 51, 163, 180]\). The set \( \Psi \) is presented in \([62]\) and \([63, 67, 173, 51, 163, 180]\). The set \( \Psi \) is presented in \([62]\) and \([63, 67, 173, 51, 163, 180]\).
times and select the first activity $A_k$ such that:
\[ r_i + p_i + \sum_{A_j \in \Psi_k} p_j > \hat{d}_k \]

If such an activity $A_k$ exists, then post the following constraints:
\[
\begin{align*}
A_i & \not\in \Psi_k \\
\text{start}(A_i) & \geq \max_{A_j \in \Psi_k} JPS(A_j)
\end{align*}
\]

where $JPS(A_j)$ is the completion time of activity $A_j$ in JPS.

Figure 8.3 presents the JPS of 3 activities. On this example, the Edge-Finding propagation algorithm deduces $\text{start}(A_1) \geq 8$ ($A_1$ must execute after $\{A_2, A_3\}$), when the Time-Table and the disjunctive constraint propagation algorithms deduce nothing.

An alternative algorithm is presented in [177, 173], also having time complexity $O(n^2)$. This algorithm is in practice easy to implement and adapt to other problems discussed later in this manuscript. The details of the algorithm are presented in Algorithm 7.

For the algorithm we assume that the set of activities $\{A_1, \ldots, A_n\}$ is ordered by ascending release dates. As such $r_i$ is the release date of the $i$–th activity according to this ordering; $r'_i$ is the adjusted value of the release date. Thanks to the introduction of the variables $r'_i$, one does not need to reorder activities inside the loops.

The outer iteration of the algorithm iterates over the deadlines of the activities. In the $k$–th iteration we consider the $k$–th activity in the ordering by ascending release dates and we refer to its deadline by $\hat{d}_k$. The idea then is to split the set of activities in two sets, $\Omega_{\leq}$ consisting of those activities having a deadline at most $\hat{d}_k$, and $\Omega_{>}$ consisting of those activities having a deadlines greater than $\hat{d}_k$. We will study finding updates of release dates for activities in this latter set.

After the first inner loop, i.e., after line 15, the following values are calculated.

- The program variable $P$ equals the sum of processing times in $\Omega_{\leq}$, i.e., $P = p_{\Omega_{\leq}}$.
- The program variable $C$ equals the maximal minimal end time of any subset of the set $\Omega_{\leq}$, i.e., $C = \max_{\emptyset \neq \Omega' \subseteq \Omega_{\leq}} r_{\Omega'} + p_{\Omega'}$

Also the program variables $C_i$ are calculated. They are close to the program variable $C$, but instead of being defined on the complete set $\Omega_{\leq}$, they are defined on the subset $\Omega_{\leq,i}$ containing the activities $A_j$ in $\Omega_{\leq}$ that come after $A_i$ in the ordering by ascending release dates. $\Omega_{\leq,i}$ thus is defined as $\{A_j \in \Omega_{\leq} : j \geq i\} = \{A_j \in \Omega : d_j \leq \hat{d}_k \land j \geq i\}$, and $C_i$ is defined as $\max_{\emptyset \neq \Omega' \subseteq \Omega_{\leq,i}} r_{\Omega'} + p_{\Omega'}$.

Lines 21-23 describe the deductions corresponding to rules 8.2 and 8.4 for the activity $A_i$ at hand and all subsets of $\Omega_{\leq,i}$. Through line 19 the program variable $P$ equals $p_{\Omega_{\leq,i}}$. So if $r_i + p_i + P$ exceeds $\hat{d}_k$, then $A_i \not\in \Omega_{\leq,i}$, and thus $r_i$ can be updated to $\max(r_i, C_i)$.

Lines 24-26 describe the deductions corresponding to rules 8.2 and 8.4 for the activity $A_i$ at hand and all subsets of $\Omega_{\leq}$ that include at least one activity $A_j$ that comes before $A_i$ in the ordering by

ascending release dates, i.e., for which \( j < i \). Through line 18 the program variable \( H \) equals the maximal minimal end time of these subsets, i.e., \( H = \max_{j<i} (r_j + p_{n_j}) \). Let \( j_{\max} \leq i \) be the index for which \( r_{j_{\max}} + p_{n_{j_{\max}}} \) is maximal. So if \( H + p_i \) exceeds \( d_k \), then \( A_i \gg \Omega_{\leq j_{\max}} \), and thus \( r_i \) can be updated to \( \max(r_i, C_{j_{\max}}) \). By definition of \( C \) and the \( C_i \)’s, \( C_{j_{\max}} = C \).

Another variant of the Edge-Finding technique is presented in [63]. It runs in \( O(n \log n) \) but requires much more complex data structures. [67] presents another variant, based on the explicit definition of “task intervals.” This variant runs in \( O(n^3) \) in the worst case, but works in an incremental fashion. Finally, [51] and [105] propose several extensions to take setup times into account.

An interesting property of the Edge-Finding technique is established in [10] and in [163]:

**Proposition 40.** Considering only the resource constraint and the current time bounds of activities, the Edge-Finding algorithm computes the smallest earliest start time at which each activity \( A_i \) could start if all the other activities were interruptible.

As shown in [154], the Edge-Finding algorithms above may perform different deductions than the more standard disjunctive constraint propagation algorithms. Each of the two techniques performs some deductions that the other technique does not perform. In practice, an Edge-Finding algorithm is often coupled with a disjunctive constraint propagation algorithm to allow a maximal amount of constraint propagation to take place. More details on this topic can be found in Chapter 4.

### 8.1.4 Not-First, Not-Last

The algorithms presented in the preceding sections focus on determining whether an activity \( A_i \) must execute first (or last) in a set of activities \( \Omega \cup \{ A_i \} \) requiring the same resource. A natural complement consists of determining whether \( A_i \) can execute first (or last) in \( \Omega \cup \{ A_i \} \). If not, \( A_i \) is “Not-First” and cannot start before at least one activity in \( \Omega \) is finished.

In the non-preemptive case, this leads to the following rules [185, 62, 67, 21, 154, 211, 87]:

\[
\forall \Omega, \forall A_i \notin \Omega, [d_i - r_i < p_{n_i}] \Rightarrow \neg(A_i \ll \Omega)
\]

\[
\forall \Omega, \forall A_i \notin \Omega, [d_i - r_i < p_{n_i} + p_i] \Rightarrow \neg(A_i \gg \Omega)
\]

\[
\forall \Omega, \forall A_i \notin \Omega, \neg(A_i \ll \Omega) \Rightarrow start(A_i) \geq estmin_{\Omega}
\]

\[
\forall \Omega, \forall A_i \notin \Omega, \neg(A_i \gg \Omega) \Rightarrow end(A_i) \leq lstmax_{\Omega}
\]

![Figure 8.4: Propagation of the Not-First Not-Last rule.](image)
O(n^2) time and O(n) space algorithm of [21] for the “Not-First” problem. The “Not-Last” problem is solved in a symmetric fashion. Alternative approaches can be found in [21, 87].

Let us first introduce some assumptions and notations. We assume that the relation \( r_i + p_i \leq d_i \) holds for every activity \( A_i \). Otherwise, the scheduling problem clearly allows no solution and the constraint propagation process can stop. We also assume that the activities \( A_1, \ldots, A_n \) which require the resource under consideration are sorted in non-decreasing order of latest end times (this can be done in \( O(n \log n) \) time). Hence, \( i \leq j \) implies \( d_i \leq d_j \). For a given \( j \) and a given \( k \), \( \Omega(j, k) \) denotes the set of indices \( m \in \{1, \ldots, k\} \) such that \( r_j + p_j \leq r_m + p_m \) and \( \Omega(i, j, k) \) denotes \( \Omega(j, k) - \{i\} \). Hence, if \( i \) does not belong to \( \Omega(j, k) \), \( \Omega(i, j, k) \) is equal to \( \Omega(j, k) \). Let \( S_{j,k} = p_{\Omega(j,k)} \) if \( j \leq k \) and \( S_{j,k} = -\infty \) otherwise. Let \( d_{j,k} = \min_{1 \leq l \leq k}(d_l - S_{j,l}) \).

**Proposition 41.** For a given \( j \), the values \( d_{j,1}, \ldots, d_{j,n} \) can be computed in \( O(n) \) time.

**Proof.** The values of \( S_{j,k} \) and \( d_{j,k} \) can be computed in constant time from the values of \( S_{j,k-1} \) and \( d_{j,k-1} \). One just has to test whether \( k \) verifies \( r_j + p_j \leq r_k + p_k \) or not.

**Proposition 42.** If the “Not-First” rules applied to activity \( A_i \) and set \( \Omega \) allow to update the earliest start time of \( A_i \) to \( r_j + p_j \) then there exists an index \( k \geq j \) such that the “Not-First” rules applied to activity \( A_i \) and set \( \Omega(i, j, k) \) allow to update the earliest start time date of \( A_i \) to \( r_j + p_j \).

**Proof.** Let \( k \) be the maximal index of the activities in \( \Omega \). \( \Omega(i, j, k) \) is included in \( \Omega(i, j, k) \) and \( d_{\Omega(i,j,k)} \) is equal to \( d_{\Omega(i,j,k)} \). Hence the rules can be applied to \( A_i \) and \( \Omega(i, j, k) \) and provide the conclusion that \( A_i \) cannot start before \( r_j + p_j \) since every \( m \) in \( \Omega(i, j, k) \) satisfies \( r_j + p_j \leq r_m + p_m \).

**Proposition 43.** Let \( i \) and \( j \) be such that \( r_i + p_i < r_j + p_j \). In this case, the “Not-First” rules allow to update the earliest start time of \( A_i \) to \( r_j + p_j \) if and only if \( r_i + p_i > d_{j,n} \).

**Proof. Necessary condition.** Let us assume that the rules allow to update the earliest start time of \( A_i \) to \( r_j + p_j \). According to Proposition 42, there exists \( k \geq j \) such that \( \Omega(i, j, k) \) is not empty and \( d_k - r_i < p_{\Omega(i,j,k)} + p_i \). Since \( r_i + p_i < r_j + p_j \) implies that \( i \) does not belong to \( \Omega(j, k) \), this implies \( r_i + p_i > d_k - S_{j,k} \geq d_{j,n} \).

**Proof. Sufficient condition.** Let us assume that \( r_i + p_i > d_{j,n} \). \( d_{j,n} \) is finite, so there exists an index \( k \geq j \) such that \( S_{j,k} = d_k - S_{j,k} \). Since \( i \) does not belong to \( \Omega(j, k) \), we have \( d_k - r_i < p_{\Omega(i,j,k)} + p_i \). So, the rules allow to update the earliest start time of \( A_i \) to the value \( r_j + p_j \).

**Proposition 44.** Let \( i \) and \( j \) be such that \( r_i + p_i \geq r_j + p_j \). In this case, the “Not-First” rules allow to update the earliest start time of \( A_i \) to \( r_j + p_j \) if and only if either \( r_i + p_i > d_{j,i-1} \) or \( r_i > d_{j,n} \).

**Proof. Necessary condition.** Let us assume that the rules allow to update the earliest start time of \( A_i \) to \( r_j + p_j \). According to Proposition 42, there exists \( k \geq j \) such that \( \Omega(i, j, k) \) is not empty and \( d_k - r_i < p_{\Omega(i,j,k)} + p_i \). Two cases, \( k < i \) and \( i < k \), can be distinguished. If \( k < i \), \( i \) does not belong to \( \Omega(j, k) \). This implies that \( r_i + p_i > d_k - S_{j,k} \geq d_{j,i-1} \). On the contrary, if \( i < k \), \( i \) belongs to \( \Omega(j, k) \). Then \( p_{\Omega(j,k)} = p_{\Omega(i,j,k)} + p_i \) and \( r_i > d_k - S_{j,k} \geq d_{j,i-1} \).

**Proof. Sufficient condition.** If \( r_i + p_i > d_{j,i-1} \), \( d_{j,i-1} \) is finite, so there exists an index \( k \), not greater than \( i \), such that \( d_{j,i-1} = d_k - S_{j,k} \). Since \( i \) does not belong to \( \Omega(j, k) \), we have \( d_k - r_i < p_{\Omega(i,j,k)} + p_i \). So, the rules allow to update the earliest start time of \( A_i \) to \( r_j + p_j \). Let us now assume that \( r_i + p_i \leq d_{j,i-1} \) and \( r_i > d_{j,n} \). Then there exists an index \( k \geq j \) such that \( d_{j,n} = d_k - S_{j,k} \). Note that \( k \geq i \) (otherwise, \( d_{j,n} = d_{j,i-1} = r_i \) contradicts \( r_i + p_i \leq d_{j,i-1} \)). Consequently, \( i \) belongs to \( \Omega(j, k) \). In addition, \( \Omega(j, k) \) is not reduced to \( \{i\} \), otherwise we would have \( r_i > d_{j,n} = d_k - S_{j,k} = d_k - p_i \geq d_i - p_i \) which contradicts the initial assumption that \( r_i + p_i \leq d_i \) for all \( i \). Hence, \( \Omega(i, j, k) \neq \emptyset \) satisfies \( d_k - r_i < p_{\Omega(i,j,k)} + p_i \). So, the rules allow to update the earliest start time of \( A_i \) to \( r_j + p_j \).

Algorithm 8 performs the time-bound adjustments corresponding to the “Not-First” rules.

**Proposition 45.** Algorithm 8 performs the time-bound adjustments corresponding to the “Not-First” rules. It runs in \( O(n^2) \) time and \( O(n) \) space.
Algorithm 8 The Not-First Algorithm

1: for $i = 1$ to $n$ do
2: \[ r_i' := r_i \]
3: end for
4: for $j = 1$ to $n$ do
5: Compute $d_{j,1}, \ldots, d_{j,n}$
6: for $i = 1$ to $n$ do
7: if $r_i + p_i < r_j + p_j$ then
8: if $r_i + p_i > d_{j,n}$ then
9: \[ r_i' := \max(r_i', r_j + p_j) \]
10: end if
11: else
12: if $r_i + p_i > d_{j,i-1}$ or $r_i > d_{j,n}$ then
13: \[ r_i' := \max(r_i', r_j + p - j) \]
14: end if
15: end if
16: end for
17: end for
18: for $i = 1$ to $n$ do
19: $r_i := r_i'$
20: end for

Proof. Propositions 43 and 44 imply that the algorithm performs exactly the deductions implied by the rules. Thanks to the introduction of the variables $r_i'$, one does not need to reorder activities inside the loops. The algorithm runs in $O(n^2)$ steps since for each $j$ in the outer loop, $O(n)$ steps are required to compute $d_{j,1} \ldots d_{j,n}$ and for each $i$ in the inner loop, $O(1)$ steps are required to perform the relevant tests. In addition, the algorithm requires a linear amount of memory space since only the values $d_{j,1} \ldots d_{j,n}$ for a given $j$ are required.

Let us note that when the processing times of activities are fixed, the “Not-First” and “Not-Last” rules subsume the disjunctive constraint propagation technique mentioned in Section 8.1.2. Hence, no disjunctive constraint propagation algorithm is needed when the “Not-First” algorithm above and its dual “Not-Last” algorithm are applied.

8.1.5 More Propagation

In [178] some supplementary ways of updating the earliest start times and latest end times are given. We illustrate these methods by way of an example. In Figure 8.5 we can observe that activity $A_1$ cannot be started at time 6. This can be seen by observing that if $A_1$ is started at time 6, at most one activity can be scheduled before $A_1$ and at most one activity can be scheduled after $A_1$. This means that one activity from the three activities $A_2$, $A_3$, and $A_4$ cannot be scheduled. In this example we can deduce that $r_1$ can be set to 8, being the earliest end time of any combination of two out of the three activities $A_2$, $A_3$, and $A_4$.

Figure 8.5: Four activities on the same machine.
More generally speaking, an activity \( A_i \) cannot start at a certain time \( t \) if there is a set \( \Omega \subseteq \{ A_1, \ldots, A_n \} \) of activities \( A_i \notin \Omega \) and a \( u, 1 \leq u \leq |\Omega| \) such that at most \( u - 1 \) activities can be scheduled before \( t \) and at most \( |\Omega| - u \) activities after \( t + p_i \). Let us define \( \text{eet}(\Omega, u) \) as the earliest end time of any subset \( \Omega' \subseteq \Omega \) such that \(|\Omega'| = u \) and \( \text{lst}(\Omega, u) \) as the latest start time of any subset \( \Omega' \subseteq \Omega \) such that \(|\Omega'| = u \). Now, if for a start time \( t \) of \( A_i, t < \text{eet}(\Omega, u) \), then at most \( u - 1 \) activities in \( \Omega \) can be scheduled before \( t \). If also \( \text{lst}(\Omega, |\Omega| - u + 1) < t + p_i \), then at most \(|\Omega| - u \) activities in \( \Omega \) can be scheduled after \( t + p_i \). In conclusion, only \(|\Omega| - u + u - 1 = |\Omega| - 1 \) activities in \( \Omega \) can be scheduled and thus \( t \) is an inconsistent start time for \( A_i \). As usual we seek only to update the earliest and latest start and end times of activities, which leads to the following proposition.

**Proposition 46.** [178] Let \( A_i \) be an activity and let \( \Omega \subseteq \{ A_1, \ldots, A_n \} \) with \( A_i \notin \Omega \). If there exists a \( u, 1 \leq u \leq |\Omega| \) such that

\[
\text{eet}(\Omega, u) \wedge \text{lst}(\Omega, |\Omega| - u + 1) < \text{eet}(A_i),
\]

then \( r_i \) can be set to \( \text{eet}(\Omega, u) \).

**Proof.** It is clear that at most \( u - 1 \) activities in \( \Omega \) can be scheduled before \( r_i \) and at most \(|\Omega| - u \) activities in \( \Omega \) can be scheduled after \( \text{eet}(A_i) \), and thus at most \(|\Omega| - 1 \) activities in \( \Omega \) can be scheduled in total when \( A_i \) is scheduled at \( r_i \). Furthermore, if \( r_i \) is set to something less than \( \text{eet}(\Omega, u) \) the same situation occurs. \( \square \)

Now any lower bound for \( \text{eet}(\Omega, u) \) and any upper bound for \( \text{lst}(\Omega, |\Omega| - u + 1) \) can be used here. Using \( \text{eet}(\Omega, u) = \text{r}_\Omega + \min_{\Omega' \subseteq \Omega: |\Omega'| = u} p_{\Omega'} \), and \( \text{lst}(\Omega, u) = \text{d}_\Omega - \min_{\Omega' \subseteq \Omega: |\Omega'| = u} p_{\Omega'} \), leads to an algorithm the time complexity of which is \( O(n^2 \log n) \).

The following improvements on this propagation method can be implemented. Suppose that in the situation of Figure 8.5 the earliest start time of activity \( A_4 \) is updated to become 6 through propagation of some other constraint, see Figure 8.6. If we simply apply the definitions given above for \( \text{eet}(\Omega, u) \) and \( \text{lst}(\Omega, u) \) we do not find an update of \( r_1 \). However, we can see that \( A_4 \) cannot be scheduled before \( A_1 \) if \( A_1 \) is scheduled at \( r_1 \). With this observation we can sharpen the calculations of \( \text{eet}(\Omega, 2) \) and \( \text{lst}(\Omega, 2) \). As a result we can deduce that the earliest start time of \( A_1 \) can be set to 9, being the earliest end time of \( A_2 \) and \( A_3 \).

![Figure 8.6: Four activities on the same machine.](image)

Yet another way to improve the propagation can be observed in Figure 8.7 where it can be seen that with the rules given so far no update of the earliest start time of \( A_1 \) is found. However, we can observe that activity \( A_2 \) cannot be scheduled alone after \( A_1 \) when \( A_1 \) is scheduled at \( r_1 \), as the earliest end time of \( A_3, A_4, \) and \( A_5 \) is 12. Activity \( A_2 \) can, furthermore, not be scheduled after \( A_1 \) together with any other activity as the time between \( \text{eet}_1 \) and \( \text{d}_{\{A_2, A_3, A_4, A_5\}} \) is 7 and the sum of \( p_2 \) and the smallest processing time of the other activities is 8. Thus, with 12 as an upper bound on the update of \( r_1 \), we can say that \( A_2 \) is to be scheduled before \( A_1 \). As the same holds for \( A_3 \), we find that we can update \( r_1 \) to become 12.

Incorporating these improvements results in an algorithm the time complexity of which is \( O(n^3) \).
8.2 Preemptive Problems

In the following sections, we study several methods to propagate the preemptive One-Machine resource constraint: A set of \( n \) interruptible activities \( \{A_1, \ldots, A_n\} \) require the same machine. First, we show that both the Time-Table mechanism and the disjunctive constraint can be extended. We then describe a resource constraint based on network flows. In the last section, a mechanism that extends the Edge-Finding mechanism to the mixed case, \( i.e., \) the case in which both interruptible and non-interruptible activities are mixed, is presented.

8.2.1 Time-Table Constraint

At the first glance, it seems that the main principle of the Time-Table mechanism directly applies to both the preemptive and the mixed case. However, an important difference appears in the relation between the variables \( X(A_i,t) = E(A_i,t), \text{set}(A_i), \text{start}(A_i), \text{end}(A_i), \text{and} \ proc(A_i) \). The earliest start time \( r_i \) can easily be set to the first time \( t \) at which \( X(A_i,t) \) can be 1. Similarly, the latest end time \( d_i \) can easily be set to 1 + the last time \( t \) at which \( X(A_i,t) \) can be 1. However, the earliest end time \( \text{eet}_i \) is computed so that there possibly exist \( \text{proc}(A_i) \) time points in \( \text{set}(A_i) \cap [r_i, \text{eet}_i] \), and the latest start time \( \text{lst}_i \) is computed so that there possibly exist \( \text{proc}(A_i) \) time points in \( \text{set}(A_i) \cap [\text{lst}_i, d_i] \). These additional propagation steps make the overall propagation process far more costly. Also, it is important to notice that \( X(A_i,t) \) cannot be set to 1 as soon as \( \text{lst}_i < \text{eet}_i \). The only situation in which \( X(A_i,t) \) can be deduced to be 1 is when no more than \( \text{proc}(A_i) \) time points can possibly belong to \( \text{set}(A_i) \). This is unlikely to occur before decisions (choices in a search tree) are made to instantiate \( \text{set}(A_i) \). Therefore, constraint propagation based on Time-Tables cannot prune much.

Given the data of Figure 8.1, the Time-Table mechanism cannot deduce anything if both activities can be interrupted. Figure 8.8 shows what happens when \( A_1 \) is not interruptible (non-int.) and \( A_2 \) is interruptible (int.). As in Figure 8.1, it is guaranteed that \( A_1 \) will execute between \( \text{lst}_1 = 1 \) and \( \text{eet}_1 = 2 \). Over this period, the corresponding resource amount is no longer available for \( A_2 \). The earliest end time of \( A_2 \) is then set to 3. Then the propagation process stops since there is no time point at which \( A_2 \) is guaranteed to execute.
8.2.2 Disjunctive Constraint Propagation

In the preemptive One-Machine case, the non-preemptive disjunctive constraint can be rewritten as follows:

\[ \text{start}(A_i) + \text{proc}(A_i) \leq \text{end}(A_j) - \text{proc}(A_j) \]

\[ \text{start}(A_j) + \text{proc}(A_j) \leq \text{end}(A_i) - \text{proc}(A_i) \]

This suggests the following preemptive disjunctive constraint:

\[ \text{start}(A_i) + \text{proc}(A_i) + \text{proc}(A_j) \leq \text{end}(A_i) \]

\[ \text{start}(A_j) + \text{proc}(A_j) + \text{proc}(A_j) \leq \text{end}(A_i) \]

\[ \text{start}(A_j) + \text{proc}(A_i) + \text{proc}(A_j) \leq \text{end}(A_i) \]

\[ \text{start}(A_j) + \text{proc}(A_j) + \text{proc}(A_j) \leq \text{end}(A_i) \]

which can serve as a complement to the Time-Table constraint. Arc-B-consistency is achieved on this additional constraint. Note that in the mixed case, the first (fourth) disjunct can be removed from the disjunction if \( A_i \) (respectively, \( A_j \)) cannot be interrupted.

![Figure 8.9: Propagation of the disjunctive constraint (preemptive case).](image)

In the example of Figure 8.9, where both activities are interruptible, \( A_2 \) necessarily interrupts \( A_1 \). The propagation of the disjunctive constraint provides \( \text{start}(A_1) \leq 1 \) and \( \text{end}(A_1) \geq 5 \).

8.2.3 Network-Flow Based Constraints

Régis [191] describes an algorithm, based on matching theory, to achieve the global consistency of the “all-different” constraint. This constraint is defined on a set of variables and constrains these variables to assume pairwise distinct values. Régis’s algorithm maintains arc-consistency on the \( n \)–ary “all-different” constraint, which is shown to be more powerful than achieving arc-consistency for the \( n(n-1)/2 \) corresponding binary “different” constraints. Basically, Régis’s algorithm consists of building a bipartite graph \( G(X,Y,E) \) where \( X \) is a set of vertices corresponding to the variables of the “all-different” constraint, \( Y \) is a set of vertices corresponding to the possible values of these variables, and \( E \) is a set of edges \((x,y), x \in X, y \in Y\), such that \((x,y) \in E\) if and only if \( y \) is a possible value for \( x \). As a result, the “all-different” constraint is satisfiable if and only if there exists a 0-1 function \( f \) on \( E \) such that:

\[
\begin{align*}
\forall x \in X, & \quad \sum_{y:(x,y) \in E} f(x,y) = 1 \\
\forall y \in Y, & \quad \sum_{x:(x,y) \in E} f(x,y) \leq 1
\end{align*}
\]

In addition, a given value \( y_j \) is a possible value for a given variable \( x_i \) if and only if there exists a 0-1 function \( f_{i,j} \) such that:

\[
\begin{align*}
\forall x \in X, & \quad \sum_{y:(x,y) \in E} f_{i,j}(x,y) = 1 \\
\forall y \in Y, & \quad \sum_{x:(x,y) \in E} f_{i,j}(x,y) \leq 1 \\
f_{i,j}(x_i,y_j) & = 1
\end{align*}
\]
The problem of finding such a function (flow) \( f \) or \( f_{i,j} \) can be solved in time polynomial in the number of variables and values. In addition, the current value of \( f \) can be used to efficiently generate \( f_{i,j} \), and to compute the new value of \( f \) when the domain of a variable changes. See [191, 192, 193] for details and extensions. Notice that when all activities have unitary processing times, Régin’s algorithm can be directly applied. In the preemptive case, this can be generalized to activities of arbitrary processing times by seeing each activity \( A_i \) as \( p_i \) sub-activities of unitary processing times 1. Then, each sub-activity has to pick a value (the time at which the sub-activity executes) and the values of the sub-activities that require a given resource have to be pairwise distinct. However, under this naive formulation, both the number of variables and the number of values would be too high for practical use. This led us to another formulation where the nodes \( x \) in \( X \) correspond to activities, and the nodes \( y \) in \( Y \) correspond to a partition of the time horizon in \( q \) disjoint intervals \( I_1 = [s_1, e_1], \ldots, I_q = [s_q, e_q] \) such that \([s_1, e_q] \) represents the complete time horizon, \( e_i = s_{i+1}, (1 \leq i < q) \), and \( \{s_1, \ldots, s_q, e_q\} \) includes all the time points at which the information available about \( X(A_i, t) \) changes (Figure 8.10 illustrates this formulation on a small example). In particular, \( \{s_1, \ldots, s_q, e_q\} \) includes all the earliest start times and latest end times of activities, but it can also include bounds of intervals over which \( X(A_i, t) \) is constrained to be 1 or 0 (in this sense, the flow model is more general than preemptive Edge-Finding described in Section 8.2.4 but it does not generalize to the mixed case). \( E \) is defined as the set of pairs \((x, y)\) such that activity \( x \) can execute during interval \( y \). The maximal capacity \( c_{\text{max}}(x, y) \) of edge \((x, y)\) is set to \( \text{length}(y) \), and the minimal capacity \( c_{\text{min}}(x, y) \) of edge \((x, y)\) is set to \( \text{length}(y) \) if \( x \) is constrained to execute over \( y \) and to 0 otherwise. As a result, the preemptive resource constraint is satisfiable if and only if there exists a function \( f \) on \( E \) such that:

\[
\begin{align*}
\forall x \in X, \quad & \sum_{y : (x, y) \in E} f(x, y) = p_x \\
\forall y \in Y, \quad & \sum_{x : (x, y) \in E} f(x, y) \leq \text{length}(y) \\
\forall e \in E, \quad & c_{\text{min}}(e) \leq f(e) \leq c_{\text{max}}(e)
\end{align*}
\]

![Figure 8.10: The network flow model.](image-url)
Similar models are commonly used in Operations Research. For example, Federgruen and Groenevelt [100] use a more general model to solve particular polynomial scheduling problems with multiple parallel resources operating at different speeds. Following [191], what we propose below is to use network flow techniques, not only to find solutions to polynomial subproblems, but also to update the domains of the variables.

To search for compatible flow $f$ (SCF), one can use a well-known algorithm such as Herz’s algorithm, as described in [111, 5]. It runs in $O(|X| * |Y| * \sum_{x \in X} p_x)$. Alternatively, one can build a variant of Jackson’s Preemptive Schedule which respects the intervals during which activities are required to execute. As shown in [10], this can be done in $O(|Y| * \log(|Y|))$. This schedule is then used as an initial (possibly incompatible) flow, repaired by Herz’s algorithm in $O(|X| * |Y| * F)$, where $F$ denotes the sum, over the activities, of the sizes of the intervals included in $[r_i, d_i]$ during which the activity $A_i$ is not allowed to execute (for reasons that are not directly related to the use of the resource by other activities).

To reduce variable domains, the most natural generalization of Régin’s algorithm consists of varying $c_{\text{min}}(e)$ and $c_{\text{max}}(e)$ for each edge $e$ in turn. Algorithm 9 updates the minimal flow $c_{\text{min}}(x, y)$ that can pass through an edge $(x, y)$. The maximal flow $c_{\text{max}}(x, y)$ is obtained in a similar fashion. It is proven in [10] that this adjustment of edge capacities (AEC) can be done for all edges $(x, y)$ in $O(|X|^2 |Y| H)$, where $H$ denotes the overall time horizon $c_q - s_1$. This complexity is reached by systematically reusing the previous flow as a start point when computing the flow $f$ with the new constraint $f(x, y) \leq w$. Then the following rules can be applied:

$$
\begin{align*}
[c_{\text{max}}(x, y) = 0] &\Rightarrow [\forall t \in y, X(x, t) = 0] \\
[c_{\text{min}}(x, y) = \text{length}(y)] &\Rightarrow [\forall t \in y, X(x, t) = 1] \\
[c_{\text{min}}(x, [s_i, e_i]) \neq 0] &\Rightarrow [\text{start}(x) \leq e_i - c_{\text{min}}(x, [s_i, e_i])] \\
[c_{\text{min}}(x, [s_i, e_i]) \neq 0] &\Rightarrow [\text{end}(x) \geq s_i + c_{\text{min}}(x, [s_i, e_i])] 
\end{align*}
$$

However, SCF and AEC are not sufficient to determine the best possible time bounds for activities. Let us consider, for example, the four activities $A_1, A_2, A_3, A_4$ defined on Figure 8.10. In this case, $c_{\text{min}}(A_1, I)$ remains equal to 0 for all $I$; yet $A_1$ cannot start after 3 and cannot end before 7. However, the flow model can be used to compute the best possible earliest end times. First, given $x$ and the intervals $y_1, \ldots, y_k$ (sorted in reverse chronological order) to which $x$ is connected, one can find the maximal integer $k$ such that there exists a compatible flow $f$ with $f(x, y_i) = 0$ for $1 \leq i < k$. Then, one can compute the minimal flow $f_{\text{min}}(x, y_k)$ through $(x, y_k)$, under the constraints $f(x, y_i) = 0$ for $1 \leq i < k$. Under these conditions, $\text{end}(x) \geq s_k + f_{\text{min}}(x, [s_k, e_k])$ provides the best possible earliest end time for $x$. It is shown in [10] that this global update of time bounds (GUTB) can be done for all activities $x$ in $O(|X|^2 |Y| H)$. As for AEC, this complexity is reached by systematically reusing the previous flow as a start point for computing the new flow when an additional capacity constraint is added.

Let us remark that the incrementality of Herz’s algorithm is a key factor for both the worst-case and the practical complexity of SCF, AEC and GUTB. Of course, strongly polynomial algorithms

---

**Algorithm 9 Adjustment of Edge Capacities (AEC)**

1. $u := c_{\text{min}}(x, y)$ and $v = c_{\text{max}}(x, y)$.
2. **while** $u \neq v$ **do**
3.   $w := \lceil(u + v)/2\rceil$
4.   **if** $f$ exists **then**
5.     $v := f(x, y)$
6.   **else**
7.     $u := w + 1$
8. **end if**
9. **end while**
10. $c_{\text{min}}(x, y) := u$

in $O(|X|^2 |Y| H)$.
(with complexity independent of the schedule duration) could also be used for the search of a compatible flow [111].

### 8.2.4 Preemptive Edge-Finding

The Edge-Finding algorithm detailed in Section 8.1.3 can be extended to take into account the preemptive case and also the mixed case (i.e., the case where interruptible and non-interruptible activities are mixed). As mentioned in Section 8.1.3, Baptiste and Martin and Shmoys [10, 163] have established an interesting property of the non-preemptive Edge-Finding technique. Considering only the resource constraint and the current time bounds of activities, the algorithm computes the earliest start time at which each activity $A_i$ could start if all the other activities were interruptible. This suggests a logical extension of the technique to preemptive and mixed cases: for each activity $A_i$ requiring the resource, if $A_i$ is not interruptible, the non-preemptive Edge-Finding bound applies; if $A_i$ is interruptible then, considering only the resource constraint and the current time bounds, it would be nice to determine the earliest start and end times between which $A_i$ could execute if all the activities were interruptible.

Let us define $\Rightarrow$ so that $A_i \Rightarrow \Omega$ means “$A_i$ ends after all activities in $\Omega$” and substitute $\Rightarrow$ for $\gg$ in the rules of the primal algorithm.

$$\forall \Omega, \forall A_i \notin \Omega, [\tilde{d}_i - r_{\Omega \cup \{A_i\}} < p_\Omega + p_i] \Rightarrow A_i \Rightarrow \Omega$$

$$\forall \Omega, \forall A_i \notin \Omega, A_i \Rightarrow \Omega \Rightarrow [\text{start}(A_i) \geq \max_{\emptyset \neq \Omega' \subseteq \Omega} (r_{\Omega'} + p_{\Omega'})]$$

When $A_i$ cannot be interrupted, these two rules remain valid (even if other activities can be interrupted) and the adjustment of $r_i$ is the same as in the non-preemptive case. When $A_i$ can be interrupted, the first rule is still valid but the second is not. However, the second rule can be replaced by a weaker one:

$$\forall \Omega, \forall A_i \notin \Omega, A_i \Rightarrow \Omega \Rightarrow [\text{end}(A_i) \geq \max_{\emptyset \neq \Omega' \subseteq \Omega} (r_{\Omega' \cup \{A_i\}} + p_{\Omega' \cup \{A_i\}})]$$

This leads to a more general primal Edge-Finding algorithm:

- Compute Jackson’s Preemptive Schedule (JPS) for the resource under consideration (cf., Section 8.1.3).

- For each activity $A_i$, compute the set $\Psi$ of the activities which are not finished at $t = r_i$ on JPS. Let $p_j^*$ be the residual processing time on the JPS of the activity $A_j$ at time $t$. Let $\Psi_k = \{A_j \in \Psi - \{A_i\} : \tilde{d}_j \leq \tilde{d}_k\}$. Take the activities of $\Psi$ in decreasing order of latest end times and select the first activity $A_k$ such that:

$$r_i + p_i + \sum_{A_j \in \Psi_k} p_j^* > \tilde{d}_k$$

If such an activity $A_k$ exists, then post the following constraints:

$$\begin{cases} A_k \succ \Psi_k \\ \text{start}(A_i) \geq \max_{A_j \in \Psi_k} \text{JPS}(A_j) \\ \text{end}(A_i) \geq r_i + p_i + \sum_{A_j \in \Psi_k} p_j^* \end{cases} \quad \text{if } A_i \text{ cannot be interrupted}$$

$$\begin{cases} A_k \succ \Psi_k \\ \text{start}(A_i) \geq \max_{A_j \in \Psi_k} \text{JPS}(A_j) \\ \text{end}(A_i) \geq r_i + p_i + \sum_{A_j \in \Psi_k} p_j^* \end{cases} \quad \text{if } A_i \text{ can be interrupted}$$

where $\text{JPS}(A_j)$ is the completion time of activity $A_j$ in JPS.

In the example of Figure 8.3, the algorithm above deduces $\text{start}(A_1) \geq 8$ if $A_1$ cannot be interrupted. It deduces $\text{end}(A_1) \geq 13$ if $A_1$ can be interrupted. It is proven in [10] that considering only the resource constraint and the current time bounds of activities, this algorithm computes:

- when $A_i$ is not interruptible: the earliest time at which $A_i$ could start if all the other activities were interruptible;
Algorithm 10 Preemptive Edge-Finding

1: for $i = 1$ to $n$ do
2:   $r'_i := r_i, \text{ eet}'_i := \text{ eet}_i$
3: end for
4: for $k := 1$ to $k := n$ do
5:   $P := 0, C := -\infty, H := -\infty$
6: for $i := n$ down to $i := 1$ do
7:   if $\bar{d}_i \leq \bar{d}_k$ then
8:     $P := P + p_i$
9:     $C := \max(C, r_i + P)$
10:    if $C > \bar{d}_k$ then
11:       there is no feasible schedule, exit
12:  end if
13: end if
14: $C_i := C$
15: end for
16: for $i := 1$ to $i := n$ do
17:   if $\bar{d}_i \leq \bar{d}_k$ then
18:     $H := \max(H, r_i + P)$
19:     $P := P - p_i$
20:   else
21:     if $r_i + P + p_i > \bar{d}_k$ then
22:       if $A_i$ can be interrupted then
23:         $\text{ eet}'_i := \max(\text{ eet}'_i, r_i + P + p_i)$
24:       else
25:         $r'_i := \max(r'_i, C_i)$
26:       end if
27:     end if
28:     if $H + p_i > \bar{d}_k$ then
29:       if $A_i$ can be interrupted then
30:         $\text{ eet}'_i := \max(\text{ eet}'_i, H + p_i)$
31:       else
32:         $r'_i := \max(r'_i, C)$
33:       end if
34:     end if
35:   end if
36: end if
37: end for
38: for $i = 1$ to $n$ do
39:   $r_i := r'_i, \text{ eet}_i := \text{ eet}'_i$
40: end for
• when \( A_i \) is interruptible: the earliest time at which \( A_i \) could end if all the other activities were interruptible.

Algorithm 7 can be modified in a similar fashion. In Algorithm 10, we assume that activities are sorted in increasing order of earliest start times. Earliest start times and earliest end times are adjusted inside the inner loop (lines 25, 32 and 23, 30). The proof that this algorithm is equivalent to the JPS-based algorithm follows the proof of Algorithm 7 (cf., Section 8.1.3). First, if \( A_i \) cannot be interrupted, the new algorithm makes the same conclusions as Algorithm 7, so the proof in Section 8.1.3 applies to the new algorithm. Let us now assume that \( A_i \) can be interrupted. It is proven in [10] that the earliest time at which \( A_i \) could end if all the other activities could be interrupted is equal to the maximal value of \( r_{\Omega \cup \{A_i\}} + p_{\Omega \cup \{A_i\}} \) for \( \Omega \) triggering the Edge-Finding rules. The earliest end times computed by the new algorithm are, when they are used, equal to \( r_{\Omega \cup \{A_i\}} + p_{\Omega \cup \{A_i\}} \) for such \( \Omega \). To prove that the best possible bound is reached, consider the two cases distinguished for Algorithm 7: if all activities \( A_u \in \Omega \) are such that \( i < u \) then either \( \Omega \) or a superset of \( \Omega \) is detected by the first test \( (r_i + P + p_i > d_k) \); if some activity \( A_u \) of \( \Omega \) is such that \( u < i \) then either \( \Omega \) or a superset of \( \Omega \) is detected by the second test \( (H + p_i > d_k) \). In both cases, a bound greater than or equal to \( r_{\Omega \cup \{A_i\}} + p_{\Omega \cup \{A_i\}} \) is found.

This algorithm can be further improved:

• When \( A_i \) can be interrupted and \( \text{set}(A_i) \) is known to contain a series of intervals \( ILB^1_i, \ldots, ILB^m_i \), \( A_i \) can be replaced by \( m + 1 \) activities \( A^1_i, \ldots, A^m_i, A'_i \), with each \( A^l_i \) forced to execute over \( ILB^l_i \) and \( A'_i \) with the same earliest start time and latest end time as \( A_i \) and a processing time equal to

\[
p_i - \sum_{l=1}^m \text{length}(ILB^l_i)
\]

where \( \text{length}(ILB^l_i) \) denotes the length of the interval \( ILB^l_i \).

• When \( A_i \) can be interrupted and either \( r_i + P = d_k \) or \( H = d_k \) in the course of the algorithm, it is certain that \( A_i \) cannot start before \( d_k \). Hence, the algorithm can also be used to update earliest start times of interruptible activities.

**Remark.** When \( A_i \) has a fixed processing time and cannot be interrupted, the computation and the use of \( C_i \) and \( C \) to compute

\[
\max_{\emptyset \neq \Omega \subseteq \Omega} (r_{\Omega'} + p_{\Omega'})
\]

serves only to avoid repeated iterations of the algorithm. Indeed, suppose a purely preemptive Edge-Finding algorithm is used and suppose \( A_i \) is not interruptible. The purely preemptive Edge-Finding algorithm uses the following rules:

\[
\forall \Omega, \forall A_i \notin \Omega, [d_i - r_{\Omega \cup \{A_i\}} < p_{\Omega} + p_i] \Rightarrow [A_i > \Omega]
\]

\[
\forall \Omega, \forall A_i \notin \Omega, [A_i > \Omega] \Rightarrow [\text{end}(A_i) \geq \max_{\Omega \subseteq \Omega'} (r_{\Omega' \cup \{A_i\}} + p_{\Omega' \cup \{A_i\}})]
\]

When constraint propagation stops, the earliest end time of \( A_i \) is set to a value \( \text{eet}_i \) such that if all activities were interruptible, there would be a schedule \( S \) of the resource such that \( A_i \) does not start before \( r_i \) and ends at \( \text{eet}_i \). If the processing time of \( A_i \) is fixed, the propagation of the constraint \( \text{start}(A_i) + \text{proc}(A_i) = \text{end}(A_i) \) guarantees that when constraint propagation stops \( r_i + p_i = \text{eet}_i \). Consequently, \( A_i \) is not interrupted in \( S \), which implies that the non-preemptive Edge-Finding algorithm cannot find a better bound for \( r_i \).
Chapter 9

Propagation of Cumulative Constraints

Cumulative resource constraints represent the fact that activities $A_i$ use some amount $cap(A_i)$ of resource throughout their execution. For a fully elastic activity $A_i$, the $cap(A_i)$ variable is not meaningful and we use a variable $E(A_i)$ that represents the global “energy” required by the activity on the resource. Of course, for a non-elastic activity, we have $E(A_i) = cap(A_i) \cdot proc(A_i)$. In all case, enough resource must be allocated to activities, i.e., $E(A_i) = \sum_t E(A_i, t)$, where $E(A_i, t)$ is the amount of resource used at $t$ by $A_i$. Recall that if $A_i$ is not an elastic activity, there are some strong relations between $E(A_i, t)$ and $X(A_i, t)$: $E(A_i, t) = X(A_i, t) \cdot cap(A_i)$ For elastic activities, we have a weaker relation between the variables: $[E(A_i, t) \neq 0] \Leftrightarrow [X(A_i, t) \neq 0]$. Generally speaking, the cumulative resource constraint can be stated as follows:

$$\forall t \sum_i E(A_i, t) \leq cap$$

In the non-preemptive case, it can be rewritten as,

$$\forall t \sum_{\text{start}(A_i) \leq t < \text{end}(A_i)} cap(A_i) \leq cap$$

and in the preemptive case as,

$$\forall t \sum_{\text{start}(A_i) \leq t < \text{end}(A_i)} X(A_i, t) \cdot cap(A_i) \leq cap$$

In the following, we note $c_i$ and $e_i$ the minimal amount of the capacity (resp. of the energy) of the resource required by $A_i$. Finally we note $C$ the maximum value in the domain of the resource capacity. In this chapter, we recall the most well-known techniques used to propagate the cumulative resource constraint. We focus on the fully elastic case in Section 9.1, on the preemptive case in Section 9.2 and, finally, on the non-preemptive case in Section 9.3.

To simplify the presentation of the theory, we sometimes refer to the “Fully Elastic Problem”, to the “Preemptive Problem” and to the “Non-Preemptive Problem”. They are the decision problems respectively induced by the fully elastic resource constraint, by the preemptive resource constraint and by the non-preemptive resource constraint, i.e., the problems of determining whether there exists a fully elastic, preemptive and non-preemptive schedule of the given activities on a resource of given capacity.

9.1 Fully Elastic Problems

The Fully Elastic Problem is closely related to the Preemptive One-Machine Problem. Actually, Proposition 47 shows that they are identical modulo a simple transformation.
Transformation 1. For any instance \( I \) of the Fully Elastic Problem, let \( F(I) \) be the instance of the Preemptive One-Machine Problem defined by \( n \) activities \( A'_1, \ldots, A'_n \) with \( \forall i, r'_i = Cr_i, d'_i = Cd_i, p'_i = c_ip_i \).

Proposition 47. For any instance \( I \) of the Fully Elastic Problem, there exists a feasible fully elastic schedule of \( I \) if and only if there exists a feasible preemptive schedule of \( F(I) \).

Proof. As usual, let \( C \) be the capacity of the resource \( R \) of the instance \( I \). Let \( R' \) be the resource of the instance \( F(I) \). We first prove that if there is a feasible fully elastic schedule of \( I \), then there is a feasible preemptive schedule of \( F(I) \). We build a schedule of \( A'_1, \ldots, A'_n \) on \( R' \) as follows. For each time \( t \) and each activity \( A_i \), schedule \( E(A_i, t) \) units of \( A'_i \) on \( R' \) as early as possible after time \( Ct \). It is obvious that at any time \( t \), for any activity \( A_i \), the number of units of \( A_i \) executed at \( t \) on \( R \) is equal to the number of units of \( A'_i \) executed between \( Ct \) and \( C(t + 1) \) on \( R' \) since this algorithm consists of cutting the schedule of \( A_1, \ldots, A_n \) into slices of one time unit and rescheduling these slices on \( R' \). Consequently, for any activity \( A'_i \), exactly \( c_ip_i \) units of \( A'_i \) are scheduled between \( Cr_i \) and \( Cd_i \) and thus the earliest start times as well as latest end times are met. A symmetric demonstration would prove that if there is a feasible preemptive schedule of \( F(I) \) then there is a feasible fully elastic schedule of \( I \).

Consider now Jackson’s Preemptive Schedule. JPS is feasible if and only if there exists a feasible preemptive schedule. Moreover, JPS can be built in \( O(n \log n) \) steps (see [55] for details). Consequently, thanks to Proposition 47 we have an \( O(n \log n) \) algorithm to solve the Fully Elastic Problem. In the following, Jackson’s Fully Elastic Schedule (JFES) denotes the fully elastic schedule obtained by applying JPS on the transformed instance and rescheduling slices as described in the proof of Proposition 47.

Thanks to Proposition 47 we can also adapt all the constraint propagation mechanisms described in Section 8.2 for the preemptive case to the fully elastic case. The general adjustment framework is:

1. Build the Preemptive One-Machine Problem instance \( F(I) \) corresponding to the fully elastic instance \( I \).

2. Apply a One-Machine preemptive constraint propagation algorithm (e.g., an algorithm relying on Time-Table, network flow, disjunctive constraint, or Edge-Finding) on activities \( A'_1, \ldots, A'_n \) of the instance \( F(I) \). As explained in Section 8.2, for each activity \( A'_i \), four time bounds can be sharpened: the earliest start time \( r'_i \), the latest possible start time \( lst'_i \), the earliest possible end time \( ee'_i \), and the latest end time \( d'_i \).

3. Update the four time bounds of each \( A_i \).

\[
\begin{align*}
   r_i &:= \left\lceil \frac{r'_i}{C} \right\rceil, \\
   lst_i &:= \left\lceil \frac{lst'_i}{C} \right\rceil, \\
   ext_i &:= \left\lceil \frac{ee'_i}{C} \right\rceil, \\
   d_i &:= \left\lceil \frac{d'_i}{C} \right\rceil
\end{align*}
\]

Note that as far as Edge-Finding is concerned, the above algorithm runs in a quadratic number of steps since steps (1) and (3) are linear and step (2) can be done in \( O(n^2) \) as detailed in Section 8.2. Note that again the Edge-Finding technique provides the best possible bounds.

Proposition 48. The time-bound adjustments made by the Edge-Finding algorithm are the best possible ones, i.e., the lower and upper bounds for the start and end time of activities can be reached by some feasible fully elastic schedules.

Proof. The same proof applies for each of the four time bounds. We focus on the earliest end time. The basic idea is to prove that for any \( A_i \), (i) there is a fully elastic schedule on which \( A_i \) can end at the earliest end time computed by the fully elastic time-bound adjustment algorithm and (ii) there is no fully elastic schedule on which \( A_i \) can end before the earliest end time computed by the algorithm. Both steps can be proven thanks to Transformation 1 and to the fact that the preemptive Edge-Finding algorithm computes the best possible time bounds for the Preemptive One-Machine Problem (cf., Section 8.2.4). \(\square\)
9.2 Preemptive Problems

Several techniques can be used to propagate cumulative preemptive resource constraints. The most simple idea is to apply the constraint propagation algorithms developed for the fully elastic case. This is of course valid since the Fully Elastic Problem can be seen as a relaxation of the Preemptive Problem. However, it might not be very efficient. The following sections are dedicated to three specific constraint propagation schemes. The first one is based on Time-Tables, the second one is an adaptation of the disjunctive constraint and finally we introduce an adjustment scheme based upon “partially elastic” schedules.

9.2.1 Time-Table Constraint

The Time-Table constraint in the preemptive cumulative case is a simple adaptation of the One-Machine preemptive case. The propagation mainly consists of maintaining arc-B-consistency on the formula:

$$\forall t \sum_{\text{start}(A_i) \leq t < \text{end}(A_i)} X(A_i, t) \cdot \text{cap}(A_i) \leq C$$

As for the One-Machine preemptive case, the relations between the variables $X(A_i, t)$, $\text{set}(A_i)$, $\text{start}(A_i)$, $\text{end}(A_i)$, and $\text{proc}(A_i)$ have to be carefully handled (cf., Section 8.2.1).

9.2.2 Disjunctive Constraint

Again the disjunctive formulation of the preemptive One-Machine resource constraint can be generalized. Consider a pair of activities $(A_i, A_j)$ that cannot overlap in time due, for instance, to resource constraints, i.e., $c_i + c_j > C$. So we have $\text{set}(A_i) \cap \text{set}(A_j) = \emptyset$ or equivalently, $\forall t, X(A_i, t) = 0 \lor X(A_j, t) = 0$.

This suggests the following preemptive disjunctive constraint:

$$[\text{cap}(A_i) + \text{cap}(A_j) \leq \text{cap}] \\
\lor [\text{start}(A_i) + \text{proc}(A_i) + \text{proc}(A_j) \leq \text{end}(A_i)] \\
\lor [\text{start}(A_i) + \text{proc}(A_i) + \text{proc}(A_j) \leq \text{end}(A_j)] \\
\lor [\text{start}(A_j) + \text{proc}(A_i) + \text{proc}(A_j) \leq \text{end}(A_i)] \\
\lor [\text{start}(A_j) + \text{proc}(A_i) + \text{proc}(A_j) \leq \text{end}(A_j)]$$

which can serve as a complement to the Time-Table constraint. Arc-B-consistency is achieved on this additional constraint.

9.2.3 Partially Elastic Relaxation

The Fully Elastic Problem is a weak relaxation of the Preemptive Problem. To try to improve the relaxation, i.e., to get better bounds, we define partially elastic schedules as fully elastic schedules to which we have added two additional constraints:

$$\forall i, \forall t \in [r_i, \tilde{d}_i], \sum_{x \leq t} E(A_i, x) \leq c_i (t - r_i)$$

$$\forall i, \forall t \in [r_i, \tilde{d}_i], \sum_{t \leq x} E(A_i, x) \leq c_i (\tilde{d}_i - t)$$

Consider a resource of capacity 3 and an activity with earliest start time 0, latest end time 10, processing time 8 and resource requirement 2. Both Gantt charts of Figure 9.1 correspond to feasible fully elastic schedules. The first one is not a feasible partially elastic schedule. Indeed, 9 units of the resource are used in $[0, 4]$, which is more than $2(4 - 0)$. The second one is a feasible partially elastic schedule.
Jackson’s Partially Elastic Schedule (JPES) is the schedule built by scheduling each activity the time points at which the activities

**Proof.**

Proposition 49. There exists a feasible partially elastic schedule if and only if JPES is a feasible partially elastic schedule.

Proof. Consider a feasible partially elastic schedule \( S \) of an instance \( I \). It is then possible to build a feasible fully elastic schedule of \( G(I) \) obtained from \( S \) by a similar transformation as Transformation 2 (i.e., for any activity \( A_i \), schedule \( A_i^1 \) at the same place as the “first \( c_i \) units” of \( A_i \) on \( S \), iterate ...). Since there is a feasible fully elastic schedule of \( G(I) \), JFES is also a feasible fully elastic schedule of \( G(I) \) (Proposition 47). Thus, JPES is a feasible partially elastic schedule of \( I \).

Since Transformation 2 is done in \( O(\sum_i p_i) \) and since the Fully Elastic Problem \( G(I) \) can be solved in \( O(\sum_i p_i \log(\sum_i p_i)) \), Proposition 49 leads to an \( O(\sum_i p_i \log(\sum_i p_i)) \) algorithm to test the existence of a feasible partially elastic schedule.

**Energetic Reasoning**

We adapt the notion of “Required Energy Consumption” defined in [158] and [159] to partially elastic activities. The required energy consumption \( W_{PE}(A_i, t_1, t_2) \) of an activity over an interval \([t_1, t_2]\) is defined as follows.

\[
W_{PE}(A_i, t_1, t_2) = c_i \max(0, p_i - \max(0, t_1 - r_i) - \max(0, d_i - t_2))
\]
We now define the overall required energy consumption $W_{PE}(t_1, t_2)$ over $[t_1, t_2]$ as the sum over all activities $A_i$ of $W_{PE}(A_i, t_1, t_2)$. Note that for $t_1 = t_2, W_{PE}(t_1, t_2)$ is defined and, under the assumption $r_i + p_i \leq \bar{d}_i$, is equal to 0.

![Figure 9.2: Required energy consumption for partially elastic schedules.](image)

As shown on Figure 9.2, the required energy consumption of the activity $A_1$ ($r_1 = 0, \bar{d}_1 = 10, p_1 = 7, c_1 = 2$) over $[2, 7]$ is $W_{PE}(A_1, 2, 7) = 2(7 - (2 - 0) - (10 - 7)) = 4$.

**Proposition 50.** There is a feasible partially elastic schedule of $I$ if and only if for any non-empty interval $[t_1, t_2]$, $W_{PE}(t_1, t_2) \leq C(t_2 - t_1)$.

**Proof.** The fact that $W_{PE}(t_1, t_2) \leq C(t_2 - t_1)$ is a necessary condition is obvious. Suppose now that there is no feasible partially elastic schedule of $I$. Then there is no feasible preemptive schedule of $F(G(I))$. Consequently, there is a set of activities $S$ of $F(G(I))$ such that between the minimum earliest start time of activities in $S$ and the maximum latest end time of activities in $S$ there is not enough “space” to schedule all activities in $S$ [55]:

$$\min_{A_i' \in S} r_i' + \sum_{A_i' \in S} r_i' > \max_{A_i' \in S} \bar{d}_i'$$

This leads to

$$\begin{cases} r_i' > C(t_2 - t_1) \\ p_i' > C(t_2 - t_1) \\ \bar{d}_i' \leq C(t_2 - t_1) \end{cases}$$

(9.1)

where $Ct_1$ is the minimum earliest start time in $S$ and $Ct_2$ the maximum latest end time in $S$ (recall that earliest start times and latest end times of activities in $S$ are multiple of $C$). Then equation 9.1 becomes:

$$\sum_i \sum_{j \in [1, p_i]} c_i > C(t_2 - t_1)$$

(9.2)

For each $i$, let us count the values of $j$ in $[1, p_i]$ such that $C(r_i + j - 1) \geq C(t_1)$ and $C(\bar{d}_i - p_i + j) \leq C(t_2)$, i.e., the number of integers in $[\max(1, t_1 + 1 - r_i), \min(p_i, t_2 + p_i - \bar{d}_i)]$. This number is equal to:

$$\max(0, 1 + \min(p_i, t_2 + p_i - \bar{d}_i) - \min(1, t_1 + 1 - r_i))$$

$$= \max(0, p_i + \min(0, t_2 - \bar{d}_i) - \max(0, t_1 - r_i))$$

$$= \max(0, p_i - \max(0, \bar{d}_i - t_2) - \max(0, t_1 - r_i))$$

Therefore, equation 9.2 becomes $\sum_i W_{PE}(A_i, t_1, t_2) > C(t_2 - t_1)$.

**A Quadratic Algorithm**

We propose a quadratic algorithm to determine whether there exists a feasible partially elastic schedule. This algorithm is derived from the algorithm used in [182] to compute the subset bound of the $m$-Machine Problem, i.e., of $P_1|r_i|T_{\text{max}}$. It consists of computing the overall required energy consumption over each interval $[r_j, \bar{d}_k]$ and to test whether this energy exceeds the energy provided...
by the resource over this interval. We prove that such tests guarantee the existence of a feasible partially elastic schedule. To achieve this proof, we study the slack function \( S_{PE}(t_1, t_2) = C(t_2 - t_1) - W_{PE}(t_1, t_2) \).

**Proposition 5.1.** Let \( t_1, t_2 \) be two integer values such that \( t_1 < t_2 \).

- If \( t_1 \) is not an earliest start time, then either \( S_{PE}(t_1 + 1, t_2) < S_{PE}(t_1, t_2) \) or \( S_{PE}(t_1 - 1, t_2) \leq S_{PE}(t_1, t_2) \).
- If \( t_2 \) is not a latest end time, then either \( S_{PE}(t_1, t_2 - 1) < S_{PE}(t_1, t_2) \) or \( S_{PE}(t_1, t_2 + 1) \leq S_{PE}(t_1, t_2) \).

**Proof.** Since the two items of the proposition are symmetric, we only prove the first item. Suppose that \( S_{PE}(t_1, t_2) \leq S_{PE}(t_1 + 1, t_2) \) and \( S_{PE}(t_1, t_2) < S_{PE}(t_1 - 1, t_2) \). Let us then define the sets

\[
\Psi = \{ i : p_i - \max(0, t_1 - r_i) - \max(0, \tilde{d}_i - t_2) < 0 \}
\]

\[
\Phi = \{ i : r_i \leq t_1 \}
\]

The equation \( S_{PE}(t_1, t_2) \leq S_{PE}(t_1 + 1, t_2) \) can be rewritten

\[
-C + \sum_{i \in \Psi} c_i (- \max(0, t_1 - r_i) + \max(0, t_1 + 1 - r_i)) \geq 0
\]

Since \( \forall i \notin \Phi, \max(0, t_1 - r_i) = 0 \) and \( \max(0, t_1 + 1 - r_i) = 0 \), it leads to:

\[
\sum_{i \in \Psi \cap \Phi} c_i (- \max(0, t_1 - r_i) + \max(0, t_1 + 1 - r_i)) \geq C
\]

which leads to

\[
\sum_{i \in \Psi \cap \Phi} c_i \geq C
\]

The equation \( S_{PE}(t_1, t_2) < S_{PE}(t_1 - 1, t_2) \) can be rewritten

\[
\sum_i c_i \max(0, p_i - \max(0, t_1 - 1 - r_i) - \max(0, \tilde{d}_i - t_2))
\]

\[
- \sum_i c_i \max(0, p_i - \max(0, t_1 - r_i) - \max(0, \tilde{d}_i - t_2)) < C
\]

which leads to

\[
\sum_{i \in \Psi} c_i (- \max(0, t_1 - 1 - r_i) + \max(0, t_1 - r_i))
\]

\[
+ \sum_{i \notin \Psi} c_i \max(0, p_i - \max(0, t_1 - 1 - r_i) - \max(0, \tilde{d}_i - t_2)) < C
\]

Hence,

\[
\sum_{i \in \Psi} c_i (- \max(0, t_1 - 1 - r_i) + \max(0, t_1 - r_i)) < C \quad (9.3)
\]

Consider now two cases.

- If \( i \in \Phi \) then \( t_1 - r_i \geq 0 \). Moreover, \( t_1 - r_i - 1 \geq 0 \) since \( t_1 \) is not an earliest start time.

- If \( i \notin \Phi \) then \( t_1 - r_i < 0 \) and \( t_1 - r_i - 1 < 0 \).

(9.3) leads to \( \sum_{\Psi \cap \Phi} c_i < C \), which contradicts \( \sum_{\Psi \cap \Phi} c_i \geq C \). \( \square \)
Proposition 52.

\[ \forall r_j, \forall \tilde{d}_k > r_j, S_{PE}(r_j, \tilde{d}_k) \geq 0 \]
\[ \iff \forall t_1, \forall t_2 > t_1, S_{PE}(t_1, t_2) \geq 0 \]
\[ \iff \text{There exists a feasible partially elastic schedule} \]

Proof. Note that if \( t_1 < \min_i r_i \), the slack strictly increases when \( t_1 \) decreases, and if \( t_2 > \max_i \tilde{d}_i \), the slack strictly increases when \( t_2 \) increases. Hence, the slack function assumes a minimal value over an interval \([t_1, t_2]\) with \( \min_i r_i \leq t_1 \leq t_2 \leq \max_i \tilde{d}_i \). We can assume that both \( t_1 \) and \( t_2 \) are integers (if \( t_1 \) is not, the function \( t \to S_{PE}(t, t_2) \) is linear between \([t_1] \) and \([t_1] \); thus either \( S_{PE}([t_1], t_2) \leq S_{PE}(t_1, t_2) \) or \( S_{PE}([t_1], t_2) \leq S_{PE}(t_1, t_2) \). Among the pairs of integer values \((t_1, t_2)\) which realize the minimum of the slack, let \((u_1, u_2)\) be the pair such that \( u_1 \) is minimal and \( u_2 \) is maximal (given \( u_1 \)). We can suppose that \( S_{PE}(u_1, u_2) < 0 \) (otherwise the proposition holds). Consequently, \( u_1 < u_2 \) and thus, according to Proposition 51, either \( u_1 \) is an earliest start time or \( S_{PE}(u_1 + 1, u_2) < S_{PE}(u_1, u_2) \) or \( S_{PE}(u_1 - 1, u_2) \leq S_{PE}(u_1, u_2) \). Since \( S_{PE}(u_1, u_2) \) is minimal, the previous inequalities lead to \( S_{PE}(u_1 - 1, u_2) = S_{PE}(u_1, u_2) \); which contradicts our hypothesis on \( u_1 \). Consequently, \( u_1 \) is an earliest start time. A symmetric demonstration proves that \( u_2 \) is a latest end time.

This proposition is of great interest since it allows us to restrict the computation of \( W_{PE} \) to intervals \([t_1, t_2]\) where \( t_1 \) is an earliest start time and \( t_2 \) is a latest end time. Before describing the algorithm, we introduce the notation \( p_i^- (t_1) \) and \( p_i^+ (t_2) \) which denote the minimal number of time units during which \( A_i \) must execute respectively after \( t_1 \) and before \( t_2 \), i.e.,

\[
\begin{align*}
    p_i^- (t_2) &= \max(0, p_i - \max(0, \tilde{d}_i - t_2)) \\
    p_i^+ (t_1) &= \max(0, p_i - \max(0, t_1 - r_i))
\end{align*}
\]

Algorithm 12 computes \( W_{PE}(t_1, t_2) \) over all relevant intervals. The basic underlying idea is that, for a given \( t_1 \), the values of \( t_2 \) at which the slope of the \( t \to W_{PE}(t_1, t) \) function changes are either of the form \( \tilde{d}_i \) or of the form \( \tilde{d}_i - p_i^+ (t_1) \). The procedure iterates on the relevant values of \( t_1 \) and \( t_2 \). Each time \( t_2 \) is modified, \( W_{PE}(t_1, t_2) \) is computed, as well as the new slope (just after \( t_2 \)) of the \( t \to W_{PE}(t_1, t) \) function. Each time \( t_1 \) is modified, the set of activities with relevant \( \tilde{d}_i - p_i^+ (t_1) \) is incrementally recomputed and resorted.

Algorithm 11 Incremental updating. Procedure \texttt{update}((\texttt{Lst}, t_1^{\text{old}}), t_1)

1: \texttt{move} = \emptyset, \texttt{no move} = \emptyset (initialize two empty lists)
2: for \( A_i \in \texttt{Lst} \) do
3:     if \( p_i^+ (t_1) > 0 \) then
4:         if \( p_i^+ (t_1) = p_i^+ (t_1^{\text{old}}) \) then
5:             add \( A_i \) to \texttt{no move}
6:         else
7:             add \( A_i \) to the list \texttt{move}
8:     end if
9: end if
10: end for
11: \texttt{Lst} = \texttt{merge}(	exttt{move}, \texttt{no move})

Let us detail Algorithm 12.

- Lines 1 and 2 initialize \( D \) and \( \texttt{Lst} \). \( D \) is the array of activities sorted in increasing order of latest end times and \( \texttt{Lst} \) is the array of activities sorted in increasing order of latest start time \((\tilde{d}_i - p_i)\).

- The main loop (line 4) consists in an iteration over all earliest start times \( t_1 \). Notice that \( t_1^{\text{old}} \) allows to keep the previous value of \( t_1 \).
Algorithm 12 Computation of $W_{PE}(t_1, t_2)$

1: $D :=$ activities sorted in increasing order of $d_i$
2: $Lst :=$ activities sorted in increasing order of $d_i - p_i$
3: $t_1^{old} := \min_i (r_i)$
4: for $t_1$ in the set of earliest start times (sorted in inc. order) do
5: \hspace{1em} update($Lst, t_1^{old}, t_1$)
6: \hspace{1em} $t_1^{old} := t_1, i^D := 0, i^{Lst} := 0$
7: \hspace{1em} $W := 0, t_2^{old} := t_1, \text{slope} := \sum_i W_{PE}(i, t_1, t_1 + 1)$
8: \hspace{1em} while $i^{Lst} < \text{length}(Lst)$ or $i^D < n$ do
9: \hspace{2em} if $i^D < n$ then
10: \hspace{3em} $t_2 := \bar{d}_{D[i^D+1]}$
11: \hspace{2em} else
12: \hspace{3em} $t_2 := \infty$
13: \hspace{2em} end if
14: \hspace{1em} if $i^{Lst} < \text{length}(Lst)$ then
15: \hspace{2em} $t_2^{Lst} := d_{Lst[i^{Lst}+1]} - p_{Lst[i^{Lst}+1]}(t_1)$
16: \hspace{2em} else
17: \hspace{2em} $t_2^{Lst} := \infty$
18: \hspace{2em} end if
19: \hspace{1em} $t_2 := \min(t_2, t_2^{Lst})$
20: \hspace{1em} if $t_2 = t_2^{Lst}$ then
21: \hspace{2em} $i^{Lst} := i^{Lst} + 1, i := Lst[i^{Lst}]$
22: \hspace{2em} else
23: \hspace{2em} $i^D := i^D + 1, i := D[i^D]$
24: \hspace{2em} end if
25: \hspace{1em} if $t_1 < t_2$ then
26: \hspace{2em} $W := W + \text{slope}(t_2 - t_2^{old})$
27: \hspace{2em} $W_{PE}(t_1, t_2) := W$ (energy over $[t_1, t_2]$)
28: \hspace{2em} $t_2^{old} := t_2$
29: \hspace{2em} $\Delta := W_{PE}(i, t_1, t_2 + 1) - 2W_{PE}(i, t_1, t_2) + W_{PE}(i, t_1, t_2 - 1)$
30: \hspace{2em} $\text{slope} := \text{slope} + \Delta$
31: \hspace{2em} end if
32: end while
33: end for
Let us now detail the procedure update(Lst,t\textsuperscript{old}$_i$,t$_i$) that reorders the array Lst in increasing order of $d_i - p_i^+(t_1)$. This procedure will be described later on.

Before starting the inner loop, a variable slope is initialized (line 7). It corresponds to the slope of the function $t \rightarrow W_{PE}(t_1, t)$ immediately after the time point $t_2\text{old}$. $t_2\text{old}$ and slope are initialized line 7 and updated lines 28 and 30.

The inner loop on $t_2$ (lines 8–32) consists in iterating on both arrays $D$ and Lst at the same time. Because both arrays are sorted, some simple operations (lines 9–19) determine the next value of $t_2$. Notice that $t_2$ can take at most $2n$ values and that $t_2$ takes all the values which correspond to a latest end time. The indices $i_D$ and $i_Lst$ correspond to the current position in arrays $D$ and $Lst$ respectively.

Lines 20 to 24 enable to increase one of the indices and to determine the activity $i$ which has induced the current iteration.

To understand lines 25 to 31, consider the following rewriting of $W_{PE}(A_i, t_1, t_2)$.

$$W_{PE}(A_i, t_1, t_2) = \begin{cases} 0 & \text{if } t_2 \leq \tilde{d}_i - p_i^+(t_1) \\
 c_i(t_2 - \tilde{d}_i + p_i^+(t_1)) & \text{if } \tilde{d}_i - p_i^+(t_1) < t_2 \leq \tilde{d}_i \\
 c_i p_i^+(t_1) & \text{if } \tilde{d}_i < t_2 
\end{cases}$$

Between two consecutive values of $t_2$ in the inner loop, the function $W_{PE}$ is linear. The required energy consumption between $t_1$ and $t_2\text{old}$ is $W$, as computed at the end of the previous iteration. In addition, the slope of $t \rightarrow W_{PE}(t_1, t)$ between $t_2\text{old}$ and $t_2$ is slope. So, the required energy consumption between $t_1$ and $t_2$ is $W + \text{slope}(t_2 - t_2\text{old})$. Then, slope is updated to take into account the non-linearity of the required energy consumption of activity $i$ at time $t_2$. Notice that the algorithm may execute several times lines 25–31 for the same values of $t_1$ and $t_2$ (e.g., if $\tilde{d}_i = \tilde{d}_j$ for some $i$ and $j$). In such a case, the slope is modified several times, with respect to all the activities inducing a non-linearity at time $t_2$.

Let us now detail the procedure update. This procedure reorders the array Lst in increasing order of $d_i - p_i^+(t_1)$. This is done in linear time. We rely on the fact that when we move from $t_1\text{old}$ to $t_1$, three cases can occur.

- Either $p_i^+(t_1)$ is null and then the required energy consumption of $A_i$ in $[t_1, t_2]$ is null; and $A_i$ can be removed;
- Or $p_i^+(t_1) = p_i^+(t_1\text{old})$ (line 4);
- Or $p_i^+(t_1) = p_i^+(t_1\text{old}) - (t_1 - t_1\text{old})$ (line 6).

Activities are taken in the initial order of Lst and are stored in either the list no move (second item) or in the list move (third item). Notice that no move is sorted in increasing order of $d_i - p_i^+(t_1\text{old}) = \tilde{d}_i - p_i^+(t_1)$. Moreover, move is sorted in increasing order of $\tilde{d}_i - p_i^+(t_1\text{old})$ but move is also sorted in increasing order of $d_i - p_i^+(t_1)$ since the difference between $p_i^+(t_1)$ and $p_i^+(t_1\text{old})$ is constant for all activities in move. This means that we only have to merge move and no move to obtain the reordered array.

The overall algorithm runs in $O(n^2)$ since (i) the initial sort can be done in $O(n \log n)$, (ii) the procedure update is basically a merging procedure which runs in $O(n)$, (iii) the initial value of slope for a given $t_1$ is computed in $O(n)$, and (iv) the inner and outer loops of the algorithm both consist in $O(n)$ iterations.

**Time-Bound Adjustments**

In this section, we provide an adjustment scheme which relies on the required energy consumptions computed in the partially elastic case. From now on, we assume that $\forall r_j \forall d_k, W_{PE}(r_j, d_k) \leq C(d_k - r_j)$. If not, we know that there is no feasible partially elastic schedule. As for other adjustments techniques, our basic idea is to try to order activities. More precisely, given an activity $A_i$ and an activity $A_k$, we examine whether $A_i$ can end before $d_k$. 

Proposition 53. For any activity $A_j$ such that $r_j < \tilde{d}_k$ and

$$W_{PE}(r_j, \tilde{d}_k) - W_{PE}(A_i, r_j, \tilde{d}_k) + c_i p_i^+(r_j) > C(\tilde{d}_k - r_j)$$

a valid lower bound of the end time of $A_i$ is:

$$\tilde{d}_k + \frac{1}{c_i} (W_{PE}(r_j, \tilde{d}_k) - W_{PE}(A_i, r_j, \tilde{d}_k) + c_i p_i^+(r_j) - C(\tilde{d}_k - r_j))$$

Proof. Notice that $W_{PE}(r_j, \tilde{d}_k) - W_{PE}(A_i, r_j, \tilde{d}_k) + c_i p_i^+(r_j)$ is the overall required energy consumption over $[r_j, \tilde{d}_k]$ when $\tilde{d}_k$ is set to $\tilde{d}_k$. If this quantity is greater than $C(\tilde{d}_k - r_j)$ then $A_i$ must end after $\tilde{d}_k$. To understand the lower bound of the end time of $A_i$, simply notice that the numerator of the expression is the number of energy units of $A_i$ which have to be shifted after time $\tilde{d}_k$. We can divide this number of units by the amount of resource required by $A_i$ to obtain a lower bound of the processing time required to execute these units.

As all values $W_{PE}(r_j, \tilde{d}_k)$ can be computed in $O(n^2)$, this mechanism leads to a simple $O(n^3)$ algorithm. For any tuple $(A_i, A_j, A_k)$, check whether $A_i$ can end before $\tilde{d}_k$ and in such a case compute the corresponding time-bound adjustment. This mechanism is described in Algorithm 13. The value $W = W_{PE}(r_j, \tilde{d}_k)$ is computed in $O(n^3)$ at lines 4–6. This is an alternative to Algorithm 12 that computes the values $W_{PE}$ in a quadratic amount of steps. In [11], an algorithm that performs all time-bound adjustments in $O(n^2 \log(|\{c_i\}|))$ is described, where $|\{c_i\}|$ is the number of distinct resource requirements. This complexity becomes quadratic when the algorithm is applied to an instance of the $m$–Machine Problem (for which $\forall i, c_i = 1$). However, this algorithm requires the use of complex data structures and is out of the scope of this chapter.

Algorithm 13 An $O(n^3)$ algorithm for partially elastic adjustments

1: for $j \in \{1,\ldots,n\}$ do
2: for $k \in \{1,\ldots,n\}$ with $r_j < \tilde{d}_k$ do
3: $W := 0$
4: for $i \in \{1,\ldots,n\}$ do
5: $W := W + W_{PE}(A_i, r_j, \tilde{d}_k)$
6: end for
7: if $W > C(\tilde{d}_k - r_j)$ then
8: there is no feasible schedule, exit
9: else
10: for $i \in \{1,\ldots,n\}$ do
11: $SL := C(\tilde{d}_k - r_j) - W + W_{PE}(A_i, r_j, \tilde{d}_k)$
12: if $SL - c_i \max(0, p_i - \max(0, r_j - r_i)) < 0$ then
13: $eel_i := \max(eel_i, \tilde{d}_k + \left(\frac{1}{c_i}(c_i p_i^+(r_j) - SL)\right)$
14: $lst_i := \min(lst_i, r_j - \left(\frac{1}{c_i}(c_i p_i^+(\tilde{d}_k) - SL)\right)$
15: end if
16: end for
17: end if
18: end for
19: end for

The $m$–Machine case

In the $m$–Machine case, i.e., when activities require exactly one unit of the resource, the partially elastic necessary condition can be compared to several results of the literature (these results are discussed in [182]). First, notice that the decision variant of the Preemptive $m$–Machine Problem is polynomial and can be formulated as a maximum flow problem (similar techniques as those depicted in Section 8.2 for the One-Machine Problem are used), see for instance [100] or [182]. As shown in
[182], solving this maximum flow problem leads to a worst case complexity of $O(n^3)$. The preemptive relaxation is strictly stronger than the fully and the partially elastic relaxations.

A comparison can also be made between the subset bound, a lower bound for the optimization variant of the $m$–Machine Problem (see for example [55, 64, 182]) and the partially elastic relaxation. An instance of the optimization variant of the $m$–Machine Problem consists of a set of activities characterized by an earliest start time $r_i$, a tail $q_i$, and a processing time $p_i$, and a resource of capacity $C = m$. The objective is to find a start time assignment $s_i$ for each activity $A_i$ such that temporal and resource constraints are met and max$_i(s_i + p_i + q_i)$ is minimal.

The subset bound is the maximum among all subsets $J$ of at least $C$ activities of the following expression, in which $R(J)$ and $Q(J)$ denote the sets of activities in $J$ having respectively the $C$ smallest earliest start times and the $C$ smallest tails.

$$\frac{1}{C} \left( \sum_{A_j \in R(J)} r_j + \sum_{A_j \in J} p_j + \sum_{A_j \in Q(J)} q_j \right)$$

[182] presents an algorithm to compute the subset bound in a quadratic number of steps. Carlier and Pinson describe an $O(n \log n + nC \log C)$ algorithm [64] which relies on a “pseudo-preemptive” relaxation of the $m$–Machine Problem. Notice that the subset bound can apply, thanks to a simple transformation, as a necessary condition of existence for the decision variant of the $m$–Machine Problem:

$$\forall J \subseteq \{A_1, \ldots, A_n\} \text{ s.t., } |J| > C, \quad \sum_{A_j \in R(J)} r_j + \sum_{A_j \in J} p_j \leq \sum_{A_j \in D(J)} d_j$$

where $D(J)$ denotes the set of activities in $J$ having the $C$ largest latest end times.

**Proposition 54.** In the $m$–Machine case, there exists a feasible partially elastic schedule if and only if the subset bound necessary condition holds.

**Proof.** First, assume that there exists a feasible partially elastic schedule. Let $J$ be any subset of at least $C$ activities. Let $r_1, r_2, \ldots, r_C$ be the $C$ smallest earliest start times of activities in $J$, and $d_1, d_2, \ldots, d_C$ be the $C$ largest latest end times of activities in $J$. Since before $r_C$, at most $C$ activities execute, and since for each of these activities $A_i$ at most $r_C - r_i$ units are executed before $r_C$, the schedule of these activities can be reorganized so that $E(A_i, t)$ is at most 1 for every $t \leq r_C$. Let us now replace each activity $A_i$ in $R(J)$ with a new activity of earliest start time $r_i$, latest end time $d_i$, and processing time $p_i + (r_i - r_1)$. A feasible partially elastic schedule of the new set of activities is obtained as a simple modification of the previous schedule, by setting $E(A_i, t) = 1$ for every $A_i$ in $R(J)$ and $t$ in $[r_1, d_1]$. The same operation can be done between $d_C$ and $d_1$ for activities in $D(J)$. We have a partially elastic schedule requiring $\sum_{A_i \in J} p_i + \sum_{A_i \in R(J)} (r_i - r_1) + \sum_{A_i \in D(J)} (d_1 - d_i)$ units of energy between $r_1$ and $d_1$. Hence, $\sum_{A_i \in J} p_i + \sum_{A_i \in R(J)} (r_1 - r_1) + \sum_{A_i \in D(J)} (d_1 - d_i) \leq C(d_1 - r_1)$. This is equivalent to the subset bound condition for $J$.

We now demonstrate the other implication. Assume that the slack $S_{PE}$ is strictly negative for some interval. Let then $[t_1, t_2]$ be the interval over which the slack is minimal and let us define $J$ as the set of activities $A_i$ such that $W_{PE}(A_i, t_1, t_2) > 0$. Notice that there are at least $C$ activities in $J$ because $r_i + p_i \leq d_i$ implies that $W_{PE}(A_i, t_1, t_2) \leq t_2 - t_1$. In addition, at most $C$ activities $A_i$ in $J$ are such that $r_i < t_1$. Otherwise, when $t_1$ is replaced by $t_1 - 1$, the slack decreases. Similarly, at most $C$ activities $A_i$ in $J$ are such that $t_2 < d_i$. Let us define $X = \{A_i \in J : r_i < t_1\}$ and $Y = \{A_i \in J : t_2 < d_i\}$. According to the previous remark, we have $|X| \leq C$ and $|Y| \leq C$. Now notice that for any activity $A_i$ in $J$, $W_{PE}(A_i, t_1, t_2) > 0$. Thus, we have:

$$W_{PE}(A_i, t_1, t_2) = \sum_{A_i \in J} (p_i - \max(0, t_1 - r_i) - \max(0, d_i - t_2))$$

This can be rewritten:

$$W_{PE}(A_i, t_1, t_2) = \sum_{A_i \in J} p_i + \sum_{A_i \in X} r_i - |X|t_1 - \sum_{A_i \in Y} d_i + |Y|t_2$$
Since $S_{PE}(t_1, t_2)$ is strictly negative, we have,

$$
\sum_{A_i \in X} r_i + (C - |X|)t_1 + \sum_{A_i \in J} p_i > \sum_{A_i \in Y} \bar{d}_j + (C - |Y|)t_2
$$

Moreover, because of the definition of $R(J)$ (resp. $D(J)$), and because $|X| \leq C$ and $|Y| \leq C$, we have $\sum_{A_i \in R(J)} r_j \geq \sum_{A_i \in X} r_j + (C - |X|)t_1$ and $\sum_{A_i \in D(J)} \bar{d}_j \leq \sum_{A_i \in Y} \bar{d}_j + (C - |Y|)t_2$. As a consequence, $\sum_{A_i \in R(J)} r_j + \sum_{A_i \in J} p_i > \sum_{A_i \in D(J)} \bar{d}_j$, which is exactly the subset bound necessary condition for the set $J$.

9.3 Non-Preemptive Problems

Many algorithms have been proposed for the propagation of the non-preemptive cumulative constraint. A representative subset of these algorithms is presented in this chapter. First, note that constraint propagation methods initially developed for the preemptive or fully elastic case can, of course, be used on non-preemptive problems. However, specific propagation methods often provide better time bounds.

9.3.1 Time-Table Constraint

In the non-preemptive cumulative case, Time-Table constraint propagation mainly consists of maintaining arc-B-consistency on the formula:

$$
\forall t \sum_{\text{start}(A_i) \leq t \leq \text{end}(A_i)} \text{cap}(A_i) \leq C
$$

Propagation between the constraints linking $X(A_i, t)$, $\text{set}(A_i)$, $\text{start}(A_i)$, $\text{end}(A_i)$, and $\text{proc}(A_i)$ is performed in the same way as in the One-Machine non-preemptive case (cf., 8.1.1).

9.3.2 Disjunctive Constraint

Two activities $A_i$ and $A_j$ such that $c_i + c_j > C$ cannot overlap in time. Hence either $A_i$ precedes $A_j$ or $A_j$ precedes $A_i$, i.e., the disjunctive constraint holds between these activities. Arc-B-consistency is then achieved on the formula

$$
[\text{cap}(A_i) + \text{cap}(A_j) \leq \text{cap}] \\
\lor [\text{end}(A_i) \leq \text{start}(A_j)] \\
\lor [\text{end}(A_j) \leq \text{start}(A_i)]
$$

9.3.3 Edge-Finding

In [175, 173, 176] the Edge-Finding techniques for the One-Machine case as discussed in Section 8.1.3 are generalized to cumulative resources. The Edge-Finding techniques for the One-Machine case identify conditions for which it can be proven that an activity must be scheduled before or after a specific subset of activities on the same machine. The techniques in [175, 173, 176] extend this to cumulative resources by considering the energy $e_i = c_i p_i$ an activity uses. Before continuing, we recall the following notations, for each subset of activities $\Omega$, $e_\Omega = \sum_{A_i \in \Omega} e_i$, $r_\Omega = \min_{A_i \in \Omega} r_i$, $e_{t_{\text{min}}\Omega} = \min_{A_i \in \Omega} e_{t_{\text{min}}} \bar{d}_i$, $d_{t_{\text{max}}\Omega} = \max_{A_i \in \Omega} \bar{d}_i$ and $\text{lst}_{t_{\text{max}}\Omega} = \max_{A_i \in \Omega} \text{lst}_i$.

Figure 9.3 shows four activities each requiring a capacity of 1, that must be scheduled on a resource with capacity 2. Observe that the sum of the energy of the activities is 27, whereas the available energy between times 0 and 10 is 20. This implies that $A_1$ cannot be started at time 0. The same holds for times 1 to 5. What can actually be deduced is that all activities in $\Omega = \{A_2, A_3, A_4\}$ end before the end of $A_1$.

The following proposition provides conditions such that it can be deduced that all activities of a set $\Omega$ end before the end or start after the start of an activity $A_i$. 

this lower bound is NP-hard, which can easily be seen by observing that the optimization variant is derived that if

The minimum of the Sequencing Problem with Release Times and Deadlines [108] is a special case of this problem disabling any start time of

Proposition 55. [173] Let \( \Omega \) be a set of activities and let \( A_i \not\in \Omega \). Then, (i) if

\[ e_{\Omega \cup \{ A_i \}} > C(d_{\Omega} - r_{\Omega \cup \{ A_i \}}), \]  

then all activities in \( \Omega \) end before the end of \( A_i \), and (ii) if

\[ e_{\Omega \cup \{ A_i \}} > C(d_{\Omega} - r_{\Omega}), \]

then all activities in \( \Omega \) start after the start of \( A_i \).

Proof. (i) Suppose all activities are scheduled and an activity in \( \Omega \) does not end before the end of \( A_i \). Then the energy that is needed between \( r_{\Omega \cup \{ A_i \}} \) and \( d_{\Omega} \) is at least \( e_{\Omega \cup \{ A_i \}} \) which, according to (9.4), is larger than the available energy \( C(d_{\Omega} - r_{\Omega \cup \{ A_i \}}) \), which leads to a contradiction. The proof of (ii) is similar to the proof of (i).

If all activities in a set \( \Omega \) end before the end of an activity \( A_i \), the earliest start time of \( A_i \) can be adjusted as follows. With \( S \) a schedule (and \( S(A_i) \) the starting time of \( A_i \) on \( S \)) we define

\[ ct(\Omega, S, cp) = \min\{ t \geq r_{\Omega} : \forall t' \geq t, \sum_{A_j \in \Omega \setminus S(A_i) \leq t' < S(A_i) + c_j} c_j \leq C - cp \} \]

as the earliest time after which, in schedule \( S \), at least a capacity of \( cp \) is available on resource \( \mu \). The minimum of \( ct(\Omega, S, c_i) \) over all schedules is a lower bound on \( r_i \). The problem of calculating this lower bound is NP-hard, which can easily be solved by observing that the optimization variant of the Sequencing Problem with Release Times and Deadlines [108] is a special case of this problem by defining \( c_i = C \) and \( c_j = C \), for all \( A_j \in \Omega \).

In [173] the following lower bound which can be computed efficiently is presented. Let \( \Omega \) be a given subset of activities, then the total energy to be scheduled in \( [r_{\Omega}, d_{\Omega}] \) is \( e_{\Omega} \). At best an energy of \( (C-c_i)(d_{\Omega} - r_{\Omega}) \) can be scheduled, without disabling any start time of \( A_i \). With

\[ rest(\Omega, c_i) = e_{\Omega} - (C-c_i)(d_{\Omega} - r_{\Omega}), \]

it is derived that if \( rest(\Omega, c_i) > 0 \), a lower bound on \( r_i \) equals

\[ r_{\Omega} + [rest(\Omega, c_i)/c_i]. \]

The condition \( rest(\Omega, c_i) > 0 \) states that the total energy \( e_{\Omega} \) that needs to be scheduled in \( [r_{\Omega}, d_{\Omega}] \) is strictly larger than the energy \( (C-c_i)(d_{\Omega} - r_{\Omega}) \), which is the energy that can be scheduled without disabling any start time of \( A_i \).

Evidently, if all activities in a set \( \Omega \) end before the end of an activity \( A_i \) then also all activities in any subset \( \Omega' \subseteq \Omega \) end before the end of \( A_i \). This leads to the observation that all start times smaller than

\[ \max_{\Omega' \subseteq \Omega : \Omega' \neq \emptyset \land rest(\Omega', c_i) > 0} r_{\Omega'} + [rest(\Omega', c_i)/c_i], \]

are inconsistent for \( A_i \). If we do this for all possible subsets \( \Omega \), we obtain

\[ \max_{\Omega \subseteq \{ A_1, \ldots, A_n \} : \Omega} \max_{\Omega' \subseteq \Omega : \Omega' \neq \emptyset \land rest(\Omega', c_i) > 0} r_{\Omega'} + [rest(\Omega', c_i)/c_i], \]

(9.5)

with

\[ \alpha \iff A_i \not\in \Omega \land C(d_{\Omega} - r_{\Omega \cup \{ A_i \}}) < e_{\Omega \cup \{ A_i \}}, \]
than

Similarly, if all activities in a set \( \Omega \) start after the start of an activity \( A_i \) then all end times larger than

\[
\min_{\Omega' \subseteq \Omega : \Omega' \neq \emptyset \wedge \text{rest}(\Omega', c_i) > 0} \tilde{d}_\Omega' - \lceil \text{rest}(\Omega', c_i)/c_i \rceil,
\]

are inconsistent for \( A_i \). If we do this for all subsets \( \Omega \), we obtain

\[
\min_{\Omega \subseteq \{A_1, \ldots, A_n\}} \min_{\Omega' \subseteq \Omega : \Omega' \neq \emptyset \wedge \text{rest}(\Omega', c_i) > 0} \tilde{d}_\Omega' - \lceil \text{rest}(\Omega', c_i)/c_i \rceil,
\]

with

\[\alpha \Leftrightarrow A_i \notin \Omega \wedge C(\tilde{d}_\Omega \cup \{A_i\}) - r_\Omega < e_{\Omega \cup \{A_i\}}\]

as an upper bound on the latest end time of activity \( A_i \). We remark that the lower bounds on earliest start times and upper bounds on latest end times given in by [62] for the One-Machine case (see Section 8.1.3) are special cases of the bounds given in [173].

[173] presents an algorithm for calculating these bounds with a time complexity equal to \( O(n^2|\{c_i\}|) \), where \(|\{c_i\}|\) is the number of distinct resource requirements. Algorithm 14 performs the same adjustments in \( O(n^2) \).

As for Algorithm 7 for this algorithm we also assume that the set of activities \( \{A_1, \ldots, A_n\} \) is ordered by ascending earliest start times. As such \( r_i \) is the earliest start time of the \( i \)-th activity according to this ordering. Also as in other algorithms we assume that the earliest start times \( r_i \) that serve as input remain unchanged during the execution of the algorithm, \( \text{i.e.} \), changes of earliest start times \( r_i \) as calculated by the algorithm are effectuated afterwards.

The outer iteration of the algorithm iterates over the latest end times of the activities. In the \( k \)-th iteration we consider the \( k \)-th activity in the ordering by ascending earliest start times and we refer to its latest end time by \( \tilde{d}_k \). The idea then is to split the set of activities in two sets, \( \Omega \leq \) consisting of those activities having a latest end time at most \( \tilde{d}_k \), and \( \Omega > \) consisting of those activities having a latest end time greater than \( \tilde{d}_k \). We will study finding updates of earliest start times for activities in this latter set.

Also as for the Algorithm 7 we define the set \( \Omega_{\leq, i} \) as containing the activities \( A_j \) in \( \Omega \leq \) that come after \( A_i \) in the ordering by ascending earliest start times. \( \Omega_{\leq, i} \) thus is defined as \( \{A_j \in \Omega_{\leq} : j \geq i\} \) (= \( \{A_j \in \Omega : \tilde{d}_j \leq \tilde{d}_k \wedge j \geq i\} \)).

After the first inner loop, \( \text{i.e.} \), after line 20, the program variable \( W \) equals the sum of energies in \( \Omega_{\leq} \), \( \text{i.e.} \), \( W = e_{\Omega_{\leq}} \). The program variables \( C_i \) equal

\[
\max_{\Omega' \subseteq \Omega_{\leq, i} : \Omega' \neq \emptyset \wedge \text{rest}(\Omega', c_i) > 0} \tilde{r}_\Omega' + \lceil \text{rest}(\Omega', c_i)/c_i \rceil.
\]

To see this is true let \( A_{j_{\text{max}}} \in \Omega_{\leq, i} \) be the activity for which \( e_{\Omega_{\leq, j_{\text{max}}} + C} r_{j_{\text{max}}} \) is maximal. In the first inner loop, \( \max W \) equals \( e_{\Omega_{\leq, j_{\text{max}}} + C} \) and \( \max \text{Est} \) equals \( r_{j_{\text{max}}} \). Through lines 13-18, one can see that if \( e_{\Omega_{\leq, j_{\text{max}}} + C} (\tilde{d}_k - r_{j_{\text{max}}}) > 0 \) then

\[
C_i = r_{j_{\text{max}}} + \lceil (e_{\Omega_{\leq, j_{\text{max}}} + C} -(C-c_i)(\tilde{d}_k - r_{j_{\text{max}}})/c_i \rceil.
\]

Now, as

\[
e_{\Omega_{\leq, j_{\text{max}}} + C} r_{j_{\text{max}}} \geq \max_{A_{j'} \in \Omega_{\leq, i}} e_{\Omega_{\leq, j'-j}} + C r_{j'},
\]

it is also trivially seen that

\[
= r_{j_{\text{max}}} + \lceil (e_{\Omega_{\leq, j_{\text{max}}} + C} -(C-c_i)(\tilde{d}_k - r_{j_{\text{max}}})/c_i \rceil \geq \max_{A_{j'} \in \Omega_{\leq, i}} r_{j'} + \lceil (e_{\Omega_{\leq, j'-j}} -(C-c_i)(\tilde{d}_k - r_{j'})/c_i \rceil.
\]

>From this follows the above given definition of \( C_i \).

24:     $W := W - e_i$
25: else
26:     if $C(\bar{d}_k - r_i) < W + e_i$ then
27:       $r_i := \max(r_i, C_i)$
28:     end if
29:   if $H < e_i$ then
30:      $restW := maxW - (C - c_i)(\bar{d}_k - maxEst)$
31:     if $restW > 0$ then
32:       $r_i := \max(r_i, maxEst + [restW/c_i])$
33:     end if
34: end if
35: end if
36: end for
37: end for
Lines 26-28 describe the deductions corresponding to (9.5) for the activity \( A_i \) at hand and all subsets of \( \Omega_{\leq,i} \). Through line 24 the program variable \( V \) equals \( e_{\Omega_{\leq,i}} \). So if \( C(\tilde{d}_k - r_j) \) is smaller than \( W + e_i \), then all activities in \( \Omega_{\leq,i} \) end before the end of \( A_i \), and thus \( r_i \) can be updated to \( \max(r_i, C_i) \).

Lines 29-34 describe the deductions corresponding to (9.5) for the activity \( A_i \) at hand and all subsets of \( \Omega_{\leq} \) that include at least one activity \( A_j \) that comes before \( A_i \) in the ordering by ascending earliest start times, i.e., for which \( j < i \).

Through line 23 the program variable \( H \) equals the minimal slack of these subsets, i.e., \( H = \min_{j < i} C(\tilde{d}_k - r_j) - e_{\Omega_{\leq,j}} \). Let \( j_{\text{min}} < i \) be the index for which \( C(\tilde{d}_k - r_{j_{\text{min}}}) - e_{\Omega_{\leq,j_{\text{min}}}} \) is minimal. So if \( H < e_i \) and \( \max W - (C - c_i)(\tilde{d}_k - \text{maxEst}) > 0 \) then all activities in \( \Omega_{\leq,j_{\text{min}}} \) end before the end of \( A_i \), and thus \( r_i \) can be updated to \( \max(r_i, \text{maxEst} + [(e_{\Omega_{\leq,j_{\text{min}}} - (C - c_i)(\tilde{d}_k - r_{j_{\text{min}}})/c_i] \). By definition this means that \( r_i \) can be updated to \( \max(r_i, \text{maxEst} + [(\max W - (C - c_i)(\tilde{d}_k - \text{maxEst})/c_i]) \).

### 9.3.4 Extended Edge-Finding

The following example introduces another lower bound on the earliest start time of an activity.

![Figure 9.4: Four activities on the same resource with capacity 2.](image)

Figure 9.4 shows four activities requiring capacity 1 which must be scheduled on a resource with capacity 2. Observe that condition (9.4) of Proposition 55 does not hold for \( A_1 \) and \( \Omega = \{A_2, A_3, A_4\} \), as the sum of the energy of the activities between times 0 and 11 is 22, whereas the available energy between times 0 and 11 is also 22. Therefore, \( e_{\Omega_{\leq,1}}(A_1) = C(\tilde{d}_1 - r_1) \), and no deduction can be made by using condition (9.4). However, if we focus on the interval \( [r_1, \tilde{d}_1] \), we observe that when \( A_1 \) is scheduled as early as possible, the sum of the energy of the activities between 1 and 11 is 21, whereas the available energy is 20. Again this implies that all activities in \( \Omega = \{A_2, A_3, A_4\} \) end before the end of \( A_1 \).

The following proposition provides conditions such that it can be deduced that all activities of a set \( \Omega \) end before the end or start after the start of an activity \( A_i \).

**Proposition 56.** [173] Let \( \Omega \) be a set of activities and let \( A_i \notin \Omega \). Then (i) if

\[
{r_i} \leq r_{\Omega} < e_\Omega, \text{ and}
\]

\[
e_{\Omega} + c_i(e_\Omega - r_{\Omega}) > C(\tilde{d}_{\Omega} - r_{\Omega}),
\]  

then all activities in \( \Omega \) end before the end of \( A_i \), and (ii) if

\[
lst_i < \tilde{d}_{\Omega} \leq \tilde{d}_i, \text{ and}
\]

\[
e_{\Omega} + c_i(\tilde{d}_{\Omega} - lst_i) > C(\tilde{d}_{\Omega} - r_{\Omega}),
\]  

then all activities in \( \Omega \) start after the start of \( A_i \).

**Proof.** (i) Suppose all activities are scheduled and an activity in \( \Omega \) does not end before the end of \( A_i \). Then the energy that is occupied between \( r_{\Omega} \) and \( \tilde{d}_{\Omega} \) is at least \( e_{\Omega} + c_i(e_\Omega - r_{\Omega}) \) which, according to (9.6), is larger than the available energy \( C(\tilde{d}_{\Omega} - r_{\Omega}) \), which leads to a contradiction. The proof of (ii) is similar to the proof of (i).
If all activities in a set $\Omega$ end before the end of an activity $A_i$, then all start times smaller than

$$\max_{\Omega \subseteq \Omega': \Omega' \neq \emptyset \land \text{rest}(\Omega', c_i) > 0} r_{\Omega'} + \left\lfloor \text{rest}(\Omega', c_i)/c_i \right\rfloor,$$

are inconsistent for $A_i$. If we do this for all subsets $\Omega$, we obtain

$$\max_{\Omega \subseteq \{A_1, \ldots, A_n\} : \alpha} \max_{\Omega' \subseteq \Omega' \neq \emptyset \land \text{rest}(\Omega', c_i) > 0} r_{\Omega'} + \left\lfloor \text{rest}(\Omega', c_i)/c_i \right\rfloor,$$

with

$$\alpha \iff A_i \notin \Omega \land r_i \leq r_{\Omega} < eet_i \land e_{\Omega} + c_i(eet_i - r_{\Omega}) > C(d_{\Omega} - r_{\Omega}),$$

as a lower bound on the earliest start time of activity $A_i$.

Similarly, if all activities in a set $\Omega$ start after the start of an activity $A_i$, then all end times larger than

$$\min_{\Omega \subseteq \Omega': \Omega' \neq \emptyset \land \text{rest}(\Omega', c_i) > 0} \tilde{d}_{\Omega'} - \left\lfloor \text{rest}(\Omega', c_i)/c_i \right\rfloor,$$

are inconsistent for $A_i$. If we do this for all subsets $\Omega$, we obtain

$$\min_{\Omega \subseteq \{A_1, \ldots, A_n\} : \alpha} \min_{\Omega' \subseteq \Omega' \neq \emptyset \land \text{rest}(\Omega', c_i) > 0} \tilde{d}_{\Omega'} - \left\lfloor \text{rest}(\Omega', c_i)/c_i \right\rfloor,$$

with

$$\alpha \iff A_i \notin \Omega \land lst_i < \tilde{d}_{\Omega} \leq \tilde{d}_i \land e_{\Omega} + c_i(\tilde{d}_{\Omega} - lst_i) > C(\tilde{d}_{\Omega} - r_{\Omega}),$$

as an upper bound on the latest end time of activity $A_i$.

[174] presents an algorithm for calculating these bounds with a time complexity equal to $O(n^3)$.

### 9.3.5 Not-First, Not-Last

Also in [175, 173, 176] the following proposition is given that provides conditions for which an activity $A_i$ must be scheduled either after at least one activity or before at least one activity of a set $\Omega$ of activities that are all to be scheduled on the same cumulative resource.

**Proposition 57.** [173] Let $\Omega$ be a set of activities and let $A_i \notin \Omega$. Then, (i) if

$$r_{\Omega} \leq r_i < eet_{min},$$

and

$$e_{\Omega} + c_i(eet_i, d_{\Omega}) - r_{\Omega}) > C(d_{\Omega} - r_{\Omega}),$$

(9.7)

then all start times smaller than $eet_{min}$, are inconsistent, and (ii) if

$$lst_{max} < d_i \leq \tilde{d}_{\Omega},$$

and

$$e_{\Omega} + c_i(d_{\Omega} - \text{max(lst}_i, r_{\Omega})) > C(d_{\Omega} - r_{\Omega}),$$

then all end times larger than $lst_{max}$, are inconsistent.

**Proof.** (i) If $A_i$ is started at time $r_i$, then no activity of $\Omega$ can be scheduled to be completed before $A_i$ as $r_i < eet_{min}$. Thus an energy $c_i(r_i - r_{\Omega})$ is occupied by no activity. Then the energy the activities in $\Omega \cup \{A_i\}$ occupy in $[r_{\Omega}, \tilde{d}_{\Omega})$ is

$$e_{\Omega} + c_i(\min(eet_i, \tilde{d}_{\Omega}) - r_{\Omega}),$$

which, with (9.7) is larger than the available energy $C(d_{\Omega} - r_{\Omega})$. Thus, $r_i$ is inconsistent for $A_i$, and the same holds for all start times smaller than $eet_{min}$. The proof of (ii) is similar to the proof of (i)
From Proposition 57 it is derived that

\[
\max_{\Omega \subseteq \{A_1, ..., A_n\} : \alpha} eet_{\Omega},
\]

with

\[
\alpha \Leftrightarrow A_i \notin \Omega \land r_\Omega \leq r_i < eet_{\Omega} \land \\
e_\Omega + c_i (\min(eet_i, \tilde{d}_\Omega) - r_\Omega) > C(\tilde{d}_\Omega - r_\Omega),
\]

is a lower bound on the earliest start time of activity \(A_i\). Similarly, it is derived that

\[
\min_{\Omega \subseteq \{A_1, ..., A_n\} : \alpha} lstmax_{\Omega},
\]

with

\[
\alpha \Leftrightarrow A_i \notin \Omega \land lstmax_{\Omega} < \tilde{d}_i \leq \tilde{d}_\Omega \land \\
e_\Omega + c_i (\max(lst_i, r_\Omega) - \tilde{d}_i) > C(\tilde{d}_\Omega - r_\Omega),
\]

is an upper bound on the latest end time of activity \(A_i\).

[174] presents an algorithm for calculating these bounds with a time complexity equal to \(O(n^3)\).

### 9.3.6 Energetic Reasoning

#### Necessary Condition of Existence

The required energy consumption as defined in Section 9.2.3 is valid whether activities can be interrupted or not. In fact, [97] and [159] propose a sharper definition of the required energy consumption that takes into account the fact that activities cannot be interrupted. This leads to a new necessary condition, called the “Left-Shift / Right-Shift” necessary condition, based on energetic reasoning as defined in [97, 159]. Given an activity \(A_i\) and a time interval \([t_1, t_2]\), \(W_{Sh}(A_i, t_1, t_2)\), the “Left-Shift / Right-Shift” required energy consumption of \(A_i\) over \([t_1, t_2]\) is \(c_i\) times the minimum of the three following durations.

- \(t_2 - t_1\), the length of the interval;
- \(p_i^+(t_1) = \max(0, p_i - \max(0, t_1 - r_i))\), the number of time units during which \(A_i\) executes after time \(t_1\) if \(A_i\) is left-shifted, \(i.e.,\) scheduled as soon as possible;
- \(p_i^-(t_2) = \max(0, p_i - \max(0, \tilde{d}_i - t_2))\), the number of time units during which \(A_i\) executes before time \(t_2\) if \(A_i\) is right-shifted, \(i.e.,\) scheduled as late as possible.

This leads to \(W_{Sh}(A_i, t_1, t_2) = c_i \min(t_2 - t_1, p_i^+(t_1), p_i^-(t_2))\). The required energy consumption of \(A_1\) over \([2, 7]\) on Figure 9.5 is 8. Indeed, at least 4 time units of \(A_1\) have to be executed in \([2, 7]\); \(i.e.,\) \(W_{Sh}(A, 2, 7) = 2 \min(5, 5, 4) = 8\).

We can now define the Left-Shift / Right-Shift overall required energy consumption \(W_{Sh}(t_1, t_2)\) over an interval \([t_1, t_2]\) as the sum over all activities \(A_i\) of \(W_{Sh}(A_i, t_1, t_2)\). We can also define the Left-Shift / Right-Shift slack over \([t_1, t_2]\): \(S_{Sh}(t_1, t_2) = C(t_2 - t_1) - W_{Sh}(t_1, t_2)\). It is obvious that if there is a feasible schedule then \(\forall t_1, \forall t_2 \geq t_1, S_{Sh}(t_1, t_2) \geq 0\).

In Section 9.2.3, we showed that for the partially elastic relaxation, it was sufficient to calculate the slack only for those intervals \([t_1, t_2]\) that are in the Cartesian product of the set of earliest start times and of the set of latest end times. In this section we show that in the Left-Shift / Right-Shift case, a larger number of intervals must be considered. On top of that, we provide a precise
characterization of the set of intervals for which the slack needs to be calculated to guarantee that no interval with negative slack exists.

Let us define the sets $O_1$, $O_2$ and $O(t)$.

$$
O_1 = \{ r_i, 1 \leq i \leq n \} \cup \{ d_i - p_i, 1 \leq i \leq n \} \cup \{ r_i + p_i, 1 \leq i \leq n \}
$$

$$
O_2 = \{ d_i, 1 \leq i \leq n \} \cup \{ r_i + p_i, 1 \leq i \leq n \} \cup \{ d_i - p_i, 1 \leq i \leq n \}
$$

$$
O(t) = \{ r_i + d_i - t, 1 \leq i \leq n \}
$$

\[\forall t_1, \forall t_2 \geq t_1, S_{Sh}(t_1, t_2) \geq 0\]

\[\iff \forall s \in O_1, \forall e \in O_2, e \geq s, S_{Sh}(s, e) \geq 0\]

\[\forall e \in O_2, \forall s \in O(e), e \geq s, S_{Sh}(s, e) \geq 0\]

To prove Proposition 58, we first need to prove some technical properties of $W_{Sh}$ (Propositions 59, 60, 61). In the following, we consider that $W_{Sh}$ is defined on $\mathbb{R}$ and equals $0$ when $t_2 \leq t_1$.

We also assume $r_i + p_i \leq d_i$ for all $i$ (otherwise a contradiction is obviously detected by constraint propagation).

\textbf{Proposition 59.} Let $A_i$ be an activity and $(t_1, t_2) \in \mathbb{R}^2$ with $t_1 < t_2$. If $t_1 \notin \{ r_i, d_i - p_i, r_i + p_i \}$ and if $t_2 \notin \{ d_i, d_i - p_i, r_i + p_i \}$, then $\Phi(h) = W_{Sh}(A_i, t_1 + h, t_2 - h)$ is linear around $0$.

\textbf{Proof.} $\Phi(h)$ can be rewritten

$$
\Phi(h) = c_i \max(0, \min(t_2 - t_1 - 2h, p_i, r_i + p_i - t_1 - h, t_2 - d_i + p_i - h)).
$$

Each of the terms $0$, $t_2 - t_1 - 2h$, $p_i$, $r_i + p_i - t_1 - h$, $t_2 - d_i + p_i - h$ is linear in $h$ and if for $h = 0$, one term only realizes $\Phi(0)$, we can be sure that a small perturbation of $h$ will have a linear effect. Assume two terms are equal and realize $\Phi(0)$. Since there are five terms, this leads us to distinguish ten cases.

1. $\Phi(0)/c_i = 0 = t_2 - t_1,$
2. $\Phi(0)/c_i = 0 = p_i,$
3. $\Phi(0)/c_i = 0 = r_i + p_i - t_1,$
4. $\Phi(0)/c_i = 0 = t_2 - d_i + p_i,$
5. $\Phi(0)/c_i = t_2 - t_1 = p_i,$
6. $\Phi(0)/c_i = t_2 - t_1 = r_i + p_i - t_1,$
7. $\Phi(0)/c_i = t_2 - t_1 = t_2 - d_i + p_i,$
8. $\Phi(0)/c_i = p_i = r_i + p_i - t_1,$

Figure 9.5: Left-Shift / Right-Shift.
9. \( \Phi(0)/c_i = p_i = t_2 - \tilde{d}_i + p_i \),
10. \( \Phi(0)/c_i = r_i + p_i - t_1 = t_2 - \tilde{d}_i + p_i \).

According to our hypotheses, all cases are impossible except (5) and (10).

- We claim that case (5) cannot occur. Since \( t_2 - t_1 = p_i \) and since this value is equal to \( \Phi(0)/c_i \), we have \( p_i < r_i + p_i - t_1 \) and \( p_i < t_2 - \tilde{d}_i + p_i \) (equality cannot occur because of our hypotheses).
  Thus, \( t_2 - t_1 = p_i > \tilde{d}_i - r_i \); which contradicts \( r_i + p_i \leq \tilde{d}_i \).

- If (10) holds, then \( r_i + p_i - t_1 - h = t_2 - \tilde{d}_i + p_i - h \). We can moreover suppose that these two terms are the only ones to realize \( \Phi(0) \) (otherwise one of the previous cases would occur).
  Around 0, \( \Phi(h) \) can be rewritten \( c_i(r_i + p_i - t_1 - h) \); which is linear.

\[ \square \]

**Proposition 60.** Let \( A_i \) be an activity and \((t_1, t_2) \in \mathbb{R}^2 \) with \( t_1 < t_2 \) and \( t_2 \notin \{\tilde{d}_i, \tilde{d}_i - p_i, r_i + p_i, r_i + \tilde{d}_i - t_1\} \), then \( \Theta(h) = W_{Sh}(A_i, t_1, t_2 - h) \) is linear around 0.

**Proof.** \( \Theta(h) \) can be rewritten

\[ \Theta(h) = c_i \max(0, \min(t_2 - t_1 - h, p_i, r_i + p_i - t_1, t_2 - \tilde{d}_i + p_i - h)) \]

Each of the terms is linear in \( h \) and if for \( h = 0 \), one term only realizes \( \Theta(h) \), we can be sure that a small perturbation of \( h \) will have a linear effect. If two terms are equal and realize \( \Theta(0) \) then either

1. \( \Theta(0)/c_i = 0 = t_2 - t_1 \) or
2. \( \Theta(0)/c_i = 0 = p_i \) or
3. \( \Theta(0)/c_i = 0 = r_i + p_i - t_1 \) or
4. \( \Theta(0)/c_i = 0 = t_2 - \tilde{d}_i + p_i \) or
5. \( \Theta(0)/c_i = t_2 - t_1 = p_i \) or
6. \( \Theta(0)/c_i = t_2 - t_1 = r_i + p_i - t_1 \) or
7. \( \Theta(0)/c_i = t_2 - t_1 = t_2 - \tilde{d}_i + p_i \) or
8. \( \Theta(0)/c_i = p_i = r_i + p_i - t_1 \) or
9. \( \Theta(0)/c_i = p_i = t_2 - \tilde{d}_i + p_i \) or
10. \( \Theta(0)/c_i = r_i + p_i - t_1 = t_2 - \tilde{d}_i + p_i \).

According to our hypotheses, all cases are impossible except (3), (5), (7), (8).

- If \( t_1 = r_i + p_i \) (3) then \( \forall h, \Theta(h) = 0 \).

- Case (5) cannot occur otherwise we would have \( p_i \leq r_i + p_i - t_1 \) and \( p_i < t_2 - \tilde{d}_i + p_i \); which contradicts \( r_i + p_i \leq \tilde{d}_i \).

- If \( t_2 - t_1 = t_2 - \tilde{d}_i + p_i = \Theta(0)/c_i \) (7) then \( \forall h, \Theta(h) = c_i \max(0, \min(t_2 - t_1 - h, p_i, r_i + p_i - t_1)) \).
  We can moreover suppose that \( t_2 - t_1 \) is the only term in the new expression to realize \( \Theta(0) \) (otherwise case (1), (5) or (6) would occur) and thus \( \Theta(h) = c_i(t_2 - t_1 - h) \) around 0.

- If \( p_i = r_i + p_i - t_1 = \Theta(0)/c_i \) (8) then \( \Theta(h) = c_i \max(0, \min(t_2 - r_i - h, p_i, t_2 - \tilde{d}_i + p_i - h)) \).
  Since \( \Theta(0) = c_i p_i > 0 \), around 0 we must have \( \Theta(h) = c_i \min(t_2 - r_i - h, p_i, t_2 - \tilde{d}_i + p_i - h) \).
  Moreover, since \( r_i \leq \tilde{d}_i - p_i \), around 0 we have \( \Theta(h) = c_i \min(p_i, t_2 - \tilde{d}_i + p_i - h) \).
  Finally, we know that \( t_2 \neq \tilde{d}_i \) thus \( p_i < t_2 - \tilde{d}_i + p_i \). Consequently, around 0, \( \Theta(h) = c_i p_i \).

\[ \square \]
Proposition 61. Let \((t_1, t_2) \in \mathbb{R}^2\) such that \(t_1 < t_2\).

- If \(t_1 \notin O_1\) and \(t_2 \notin O_2\), \(h \rightarrow S_{Sh}(t_1 + h, t_2 - h)\) is linear around 0.
- If \(t_2 \notin O_2 \cup O(t_1)\), \(h \rightarrow S_{Sh}(t_1, t_2 - h)\) is linear around 0.
- If \(t_1 \notin O_1 \cup O(t_2)\), \(h \rightarrow S_{Sh}(t_1 + h, t_2)\) is linear around 0.

Proof. We prove the first item. Since \(t_1 \notin O_1\) and \(t_2 \notin O_2\), \(\forall i, h \rightarrow W_{Sh}(A_i, t_1 + h, t_2 - h)\) is linear around 0 (Proposition 59). Thus, \(h \rightarrow S_{Sh}(t_1 + h, t_2 - h)\) is linear around 0. The same proof applies for other items (Proposition 60 and its symmetric counterpart are used).

Proof of Proposition 58. The implication from left to right is obvious. Suppose now that the right hand side of the equivalence holds and that there exists an interval \([t_1, t_2]\) for which the slack is strictly negative. As in the partially elastic case, we remark that when \(t_1\) is smaller than \(r_{\min} = \min(r_i)\), the slack strictly increases when \(t_1\) decreases. Similarly, when \(t_2\) is greater than \(d_{\max} = \max(d_i)\), the slack strictly increases when \(t_2\) increases. Since the slack function is also continuous, it assumes a minimal value over an interval \([t_1, t_2]\) with \(r_{\min} \leq t_1 \leq t_2 \leq d_{\max}\). Let us consequently select a pair \((t_1, t_2)\) at which the slack is minimal. In case several pairs \((t_1, t_2)\) minimize the slack, an interval with maximal length is chosen. Since this slack is strictly negative, we must have \(t_1 < t_2\).

- **Case 1:** If \(t_1 \notin O_1\) and \(t_2 \notin O_2\), then according to Proposition 61, the function \(q(h) = S_{Sh}(t_1 + h, t_2 - h)\) is linear around 0. Since \((t_1, t_2)\) is a global minimum of the slack, \(q(h)\) is constant around 0, which contradicts the fact that the length of \([t_1, t_2]\) is maximal.

- **Case 2:** If \(t_1 \in O_1\) then \(t_2 \notin O_2 \cup O(t_1)\), otherwise the slack is non-negative. According to Proposition 61, \(q(h) = S_{Sh}(t_1, t_2 - h)\) is linear around 0. Since \((t_1, t_2)\) is a global minimum of the slack, \(q(h)\) is constant around 0, which contradicts the fact that the length of \([t_1, t_2]\) is maximal.

- **Case 3:** If \(t_2 \in O_2\) then \(t_1 \notin O_1 \cup O(t_2)\), otherwise the slack is non-negative. According to Proposition 61, \(q(h) = S_{Sh}(t_1 + h, t_2)\) is linear around 0. Since \((t_1, t_2)\) is a global minimum of the slack, \(q(h)\) is constant around 0, which contradicts the fact that the length of \([t_1, t_2]\) is maximal.

The combination of cases 1, 2 and 3 leads to a contradiction.

Proposition 58 provides a characterization of interesting intervals over which the slack must be computed to ensure it is always non-negative over any interval. This characterization is weaker than the one proposed for the partially elastic case where the interesting time intervals \([t_1, t_2]\) are in the Cartesian product of the set of the earliest start times and of the set of latest end times. However, there are still only \(O(n^2)\) relevant pairs \((t_1, t_2)\) to consider. Some of these pairs belong to the Cartesian product \(O_1 \times O_2\). The example of Figure 9.6 proves that some pairs do not. In this example, (resource of capacity 2 and 5 activities \(A_1, A_2, A_3, A_4, A_5\)), the pair \((1, 9)\) corresponds to the minimal slack and does not belong to \(\{0, 1, 4, 5, 6\} \times \{4, 5, 6, 8, 10\}\). In this interval, the slack is negative, which proves that there is no feasible schedule. Notice that neither the fully elastic nor the partially elastic relaxation can trigger a contradiction.

### Computing Energy in Quadratic time

We propose an \(O(n^2)\) algorithm to compute the required energy consumption \(W_{Sh}\) over all interesting pairs of time points. Actually, the algorithm first computes all the relevant values taken by \(W_{Sh}\) over time intervals \([t_1, t_2]\) with \(t_1 \in O_1\), and then computes all the relevant values taken by \(W_{Sh}\) over time intervals \([t_1, t_2]\) with \(t_2 \in O_2\). The characterization obtained in the previous section ensures
As for partially elastic adjustments, the values of \( T \)-Bound Adjustments activity order. Then, we consider the function to maintain the slope of the function delimited by the values \( d_i, r_i + p_i, \hat{d}_i - p_i \) and \( r_i + \hat{d}_i - t_1 \). We rely on this property to incrementally maintain the slope of the function \( t \rightarrow W_{Sh}(A_i, t_1, t) \).

There are some few differences with the partially elastic case.

- The computation of \( t_2 \) is slightly more complex since there are more interesting values to consider.
- One does not need to reorder any list: when \( t_1 \) increases, none of the values \( \hat{d}_i, r_i + p_i, \hat{d}_i - p_i \) and \( r_i + \hat{d}_i - t_1 \) changes except the last one; which corresponds to the list Middle. Since Middle is initially sorted in increasing order of \( r_i + \hat{d}_i \), it is also sorted in increasing order of \( r_i + d_i - t_1 \).
- In line 43, one shall in fact be careful not to update the slope more than once for the same tuple \( (t_1, t_2, i) \). This can be done easily by marking the activity \( A_i \) with \( t_2 \). We have not included this marking in the pseudo-code to keep it simple.

### Time-Bound Adjustments

As for partially elastic adjustments, the values of \( W_{Sh} \) can be used to adjust time bounds. Given an activity \( A_i \) and a time interval \( [t_1, t_2] \) with \( t_2 < d_i \), we examine whether \( A_i \) can end before \( t_2 \).

**Proposition 62.** If there is a time interval \( [t_1, t_2] \) such that

\[
W_{Sh}(t_1, t_2) - W_{Sh}(A_i, t_1, t_2) + c_ip_i^+(t_1) > C(t_2 - t_1)
\]

then a valid lower bound of the end time of \( A_i \) is:

\[
t_2 + \frac{1}{c_i}(W_{Sh}(t_1, t_2) - W_{Sh}(A_i, t_1, t_2) + c_ip_i^+(t_1) - C(t_2 - t_1))
\]

**Proof.** Similar to proof of Proposition 53: \( A_i \) cannot be finished before \( t_2 \) and at least

\[
W_{Sh}(t_1, t_2) - W_{Sh}(A_i, t_1, t_2) + c_ip_i^+(t_1) - C(t_2 - t_1)
\]

units of energy must come after \( t_2 \).\[\]

Figure 9.6: Some relevant time intervals are outside \( O_1 * O_2 \)
Algorithm 15 Computation of $W_{Sh}(t_1, t_2)$

1: $D :=$ activities sorted in increasing order of $d_i$
2: $Eet :=$ activities sorted in increasing order of $r_i + p_i$
3: $Lst :=$ activities sorted in increasing order of $d_i - p_i$
4: $Middle :=$ activities sorted in increasing order of $r_i + d_i$
5: for $t_1$ in the set $O_1$ (sorted in increasing order) do
6:   $i_D := 0, i_{Eet} := 0, i_{Lst} := 0, i_{Middle} := 0$
7:   $W := 0, t_1^0 := t_1, \text{slope} := \sum W_{Sh}(i, t_1, t_1 + 1)$
8:   while $i_D < n$ or $i_{Eet} < n$ or $i_{Lst} < n$ or $i_{Middle} < n$ do
9:     if $i_D < n$ then
10:        $t_2^D := \bar{d}_{D[i_D+1]}$
11:     else
12:        $t_2^D := \infty$
13:        end if
14:     if $i_{Eet} < n$ then
15:        $t_2^{Eet} := r_{Eet[i_{Eet+1}]} + p_{Eet[i_{Eet+1}]}$
16:     else
17:        $t_2^{Eet} := \infty$
18:        end if
19:     if $i_{Lst} < n$ then
20:        $t_2^{Lst} := \bar{d}_{Lst[i_{Lst+1}]} - p_{Lst[i_{Lst+1}]}$
21:     else
22:        $t_2^{Lst} := \infty$
23:        end if
24:     if $i_{Middle} < n$ then
25:        $t_2^{Middle} := r_{Middle[i_{Middle+1}]} + \bar{d}_{Middle[i_{Middle+1}]} - t_1$
26:     else
27:        $t_2^{Middle} := \infty$
28:        end if
29:     $t_2 := \min(t_2^D, t_2^{Eet}, t_2^{Lst}, t_2^{Middle})$
30:     if $t_2 = t_2^D$ then
31:        $i_D := i_D + 1, i := D[i_D]$
32:     else if $t_2 = t_2^{Eet}$ then
33:        $i_{Eet} := i_{Eet} + 1, i := Eet[i_{Eet}]$
34:     else if $t_2 = t_2^{Lst}$ then
35:        $i_{Lst} := i_{Lst} + 1, i := Lst[i_{Lst}]$
36:     else if $t_2 = t_2^{Middle}$ then
37:        $i_{Middle} := i_{Middle} + 1, i := Middle[i_{Middle}]$
38:     end if
39:     if $t_1 < t_2$ then
40:        $W := W + \text{slope}(t_2 - t_1^0)$
41:        $W_{Sh}(t_1, t_2) := W$ (energy over $[t_1, t_2]$)
42:        $t_1^0 := t_2$
43:        $\text{slope} := \text{slope} + W_{Sh}(i, t_1, t_2 + 1) - 2W_{Sh}(i, t_1, t_2) + W_{Sh}(i, t_1, t_2 - 1)$
44:     end if
45: end while
46: end for
Similarly, when
\[
W_{Sh}(t_1, t_2) - W_{Sh}(A_i, t_1, t_2) + c_i \min(t_2 - t_1, p_i^+(t_1)) > C(t_2 - t_1),
\]

\(A_i\) cannot start before \(t_1\) and a valid lower bound of the start time of \(A_i\) is
\[
t_2 - \frac{1}{c_i} (C(t_2 - t_1) - W_{Sh}(t_1, t_2) + W_{Sh}(A_i, t_1, t_2)).
\]

There is an obvious \(O(n^3)\) algorithm to compute all the adjustments corresponding to Proposition 62 which can be obtained on the intervals \([t_1, t_2]\) which correspond to potential local minima of the slack function. There are \(O(n^2)\) intervals of interest and \(n\) activities which can be adjusted. Given an interval and an activity, the adjustment procedure runs in \(O(1)\). The overall complexity of the algorithm is then \(O(n^3)\). An interesting open question is whether there is a quadratic algorithm to compute all the adjustments on the \(O(n^2)\) intervals under consideration.

**Algorithm 16** An algorithm for Left-Shift / Right-Shift adjustments

1: for all relevant time-intervals \([t_1, t_2]\) (cf., Proposition 58) do  
2: \(W := 0\)  
3: for \(i \in \{1, \ldots, n\}\) do  
4: \(W := W + c_i \min(t_2 - t_1, p_i^+(t_1), p_i^-(t_2))\)  
5: end for  
6: if \(W > C(t_2 - t_1)\) then  
7: there is no feasible schedule, exit  
8: else  
9: for \(i \in \{1, \ldots, n\}\) do  
10: \(SL := C(t_2 - t_1) - W + c_i \min(t_2 - t_1, p_i^+(t_1), p_i^-(t_2))\)  
11: if \(SL < c_i p_i^+(t_1)\) then  
12: \(eet_i := \max(eet_i, t_2 + [(c_i p_i^+(t_1) - SL)/c_i])\)  
13: end if  
14: if \(SL < c_i p_i^-(t_2)\) then  
15: \(lst_i := \min(lst_i, t_1 - [(c_i p_i^-(t_2) - SL)/c_i])\)  
16: end if  
17: end for  
18: end if  
19: end for

Note that these Left-Shift / Right-Shift adjustments are more powerful than the adjustments based on partially elastic schedules but they are also more expensive and they only apply to “non-elastic non-preemptive problems.” Note also that the satisfiability tests are such that they provide the same answers when an activity \(A_i\), which requires \(c_i\) units of the resource, is replaced by \(c_i\) activities \(A_{ij}\), each of which requires one unit of the resource. This is not true for the time-bound adjustments. Several questions are still open at this point.

- First, for the Left-Shift / Right-Shift technique, we have shown that the energetic tests can be limited to \(O(n^2)\) time intervals. We have also provided a precise characterization of these intervals. However, it could be that this characterization can be sharpened in order to eliminate some intervals and reduce the practical complexity of the corresponding algorithm.
- Second, it seems reasonable to think that our time-bound adjustments could be sharpened. Even though the energetic tests can be limited (without any loss) to a given set of intervals, it could be that the corresponding adjustment rules cannot.
Chapter 10

Comparison of Propagation Techniques

Many deductive rules and algorithms have been presented. The aim of this chapter is to compare the deductive power of these rules and algorithms, thereby providing a much clearer overview of the state of the art in the field.

10.1 Constraint Propagation Rules

The first step to allow a comparison of different constraint propagation techniques is to describe these techniques under a common, precise and unambiguous formalism. Here, most of the resource constraint propagation techniques from the preceding chapters are recalled as rules to be applied until quiescence is reached. Some rules state that arc-consistency or arc-B-consistency must be maintained on a particular mathematical formula. Others are stated as a “condition ⇒ conclusion” pair, meaning that the conclusion must be deduced whenever the condition is verified.

Each rule is identified with a two-part name XX-*, where the first part XX identifies the most general case in which the rule applies. Five cases are distinguished: FE for Fully Elastic, CP for Cumulative Preemptive, CNP for Cumulative Non-Preemptive, 1P for One-Machine Preemptive, and 1NP for One-Machine Non-Preemptive.

In the fully elastic case (FE), the amount of resource \( R \) assigned to an activity \( A_i \) can, at any time \( t \), pick any value \( E(A_i, t; R) \) between 0 and the resource capacity \( \text{cap}(R) \), provided that the sum over time of the assigned capacity \( E(A_i, t; R) \) equals a given amount of energy \( E(A_i, R) \). For each activity \( A_i \), the following constraints apply:

\[
\begin{align*}
\text{start}(A_i) & = \min_{t \in \text{set}(A_i)} (t) \\
\text{end}(A_i) & = \max_{t \in \text{set}(A_i)} (t + 1) \\
\text{proc}(A_i) & = |\text{set}(A_i)| \\
[X(A_i, t) = 1] & \iff [t \in \text{set}(A_i)] \\
[E(A_i, t, R) \neq 0] & \iff [X(A_i, t) \neq 0] \\
\sum_i E(A_i, t, R) & = E(A_i, R) \\
\sum_i E(A_i, t, R) & \leq \text{cap}(R)
\end{align*}
\]

The fully elastic case is interesting because the constraint propagation techniques that are developed for this case can be applied to any fully elastic, partially elastic, or non-elastic scheduling problem (because it is the less constrained).
In the **cumulative preemptive case** (CP), an additional constraint specifies that, for each activity $A_i$, the amount of resource $\text{cap}(A_i, R)$ assigned to $A_i$ whenever $A_i$ executes does not vary and:

$$E(A_i, t, R) = \text{cap}(A_i, R)X(A_i, t)$$

The **One-Machine preemptive case** (1P) is the restriction of the CP case to a resource of capacity 1, i.e., $\text{cap}(A_i, R) = \text{cap}(R) = 1$.

Finally, the **cumulative non-preemptive case** (CNP) and the **One-Machine non-preemptive case** (1NP) are obtained from CP and 1P by adding, for each activity $A_i$, a constraint which specifies that $A_i$ cannot be interrupted:

$$\text{set}(A_i) = [\text{start}(A_i), \text{end}(A_i)]$$

As already mentioned, constraint propagation rules developed for the FE case can be applied in the CP, 1P, CNP and 1NP cases. Similarly, constraint propagation rules developed for the CP case can be applied in the 1P, CNP and 1NP cases. In the 1NP cases, all the rules, including those developed for the 1P and CNP cases, can be applied.

To keep things simple, it is in all cases assumed that, for every activity $A_i$, the processing time $\text{proc}(A_i)$ and the energy requirement $E(A_i, R)$ are constrained to be strictly positive. We recall some notations:

- $p_i$ is the processing time of activity $A_i$, i.e., the value of $\text{proc}(A_i)$ when $\text{proc}(A_i)$ is bound. When $\text{proc}(A_i)$ is not bound, constraint propagation rules can usually be applied with $p_i$ equal to the minimal value in the domain of $\text{proc}(A_i)$.

- $c_{i,R}$ is the capacity (of the resource $R$ under consideration) required by activity $A_i$, i.e., the value of $\text{cap}(A_i, R)$ when $\text{cap}(A_i, R)$ is bound. When $\text{cap}(A_i, R)$ is not bound, constraint propagation rules can usually be applied with $c_{i,R}$ equal to the minimal value in the domain of $\text{cap}(A_i, R)$.

- $e_{i,R}$ is the energy (of the resource $R$ under consideration) required by activity $A_i$, i.e., the value of $E(A_i, R)$ when $E(A_i, R)$ is bound. When $E(A_i, R)$ is not bound, constraint propagation rules can usually be applied with $e_{i,R}$ equal to the minimal value in the domain of $E(A_i, R)$.

- $r_\Omega$ is the release date of the set of activities $\Omega$. $r_\Omega = \min_{A_i \in \Omega} r_i$.

- $\bar{d}_\Omega$ is the deadline of the set of activities $\Omega$. $\bar{d}_\Omega = \max_{A_i \in \Omega} \bar{d}_i$.

- $\text{eetmin}_\Omega$ is the smallest value in $\{\text{eet}_i : A_i \in \Omega\}$.

- $\text{lstmax}_\Omega$ is the largest value in $\{\text{lst}_i : A_i \in \Omega\}$.

- $p_\Omega$ is the processing time of the set of activities $\Omega$. $p_\Omega = \sum_{A_i \in \Omega} p_i$.

- $e_\Omega$ is the energy required by the set of activities $\Omega$. $e_\Omega = \sum_{A_i \in \Omega} e_i$.

A constraint propagation rule $\mathcal{R}$ is said to be “dominated” by another constraint propagation rule $\mathcal{R}'$ (or by a set of constraint propagation rules $\mathcal{S}$) if and only if all the deductions made by $\mathcal{R}$ are also made by $\mathcal{R}'$ (respectively, $\mathcal{S}$). Let us note that a dominated constraint propagation rule $\mathcal{R}$ can still prove useful in practice, for example when the rule $\mathcal{R}'$ that dominates $\mathcal{R}$ is too costly to be applied in a systematic fashion. Yet, knowing that $\mathcal{R}$ is dominated by $\mathcal{R}'$ can be very useful, especially when developing a search algorithm based on constraint propagation results. Indeed, we know in this case that the search tree obtained when $\mathcal{R}$ and $\mathcal{R}'$ are both applied, and the search tree obtained when $\mathcal{R}'$ alone is applied, are identical. In other terms, applying $\mathcal{R}$ when $\mathcal{R}'$ is already applied will not save any search when $\mathcal{R}$ is dominated by $\mathcal{R}'$. Conversely, knowing that two rules $\mathcal{R}$ and $\mathcal{R}'$ do not dominate each other suggests that the $(\mathcal{R} + \mathcal{R}')$ combination might perform better than each of the two rules considered separately.

Let us note that, in some scheduling problems, resource capacity varies over time (e.g., when less people work at night than during the day). When only $c < \text{cap}(R)$ resource units are available over an
interval \([t_1, t_2]\), a “fake” activity can be introduced and said to require capacity \(cap(R) - c\) between \(t_1\) and \(t_2\). This transformation will have an impact on the deductive power of some constraint propagation techniques (but not all). However, the dominance relations remain the same.

In the following, we do not consider the possible interactions between resources \(R\) so, to simplify notation, the index \(R\) will be omitted. \(C, c_i, e_i, p_i\) denote the capacity of the resource, the capacity required by activity \(A_i\), the energy required by activity \(A_i\) and the processing time of activity \(A_i\).

To keep the presentation simple, we assume that the variables \(p, \text{cap} \) and \(e\) are bound to these values. Depending on the context, it shall be obvious whether \(C, c_i, e_i\) and \(p_i\) can be replaced by the lower or the upper bound of the corresponding variables.

### 10.1.1 Time-Table Constraints

**FE-TT, CP-TT and CNP-TT:** Time-Tables in the fully elastic, preemptive and non-preemptive cases

This constraint propagation technique consists of maintaining arc-B-consistency on the constraint \(\sum_i E(A_i, t) \leq C\) and using the maximal values \(ub(E(A_i, t))\) of \(E(A_i, t)\) to compute the earliest and latest start and end times of activities:

\[
\begin{align*}
start(A_i) & \geq \min\{t : ub(E(A_i, t)) > 0\} \\
end(A_i) & \geq \min\{t : \sum_{u<t} ub(E(A_i, u)) \geq e_i\} \\
start(A_i) & \leq \max\{t : \sum_{u\geq t} ub(E(A_i, u)) \geq e_i\} \\
end(A_i) & \leq \max\{t : ub(E(A_i, t)) > 0\} + 1
\end{align*}
\]

The FE, CP and CNP cases must be distinguished because the relations between \(E(A_i, t)\) and the start and end time variables differ. In the non-preemptive case, \(E(A_i, t)\) is equal to \(c_i\) for every \(t\) in \([\text{lst}_i, \text{etc}._i]\). In the preemptive case, either the user or a search procedure must explicitly decide at which time points each activity executes. However, when \(\text{start}(A_i), \text{proc}(A_i)\) and \(\text{end}(A_i)\) are bound to values such that \(\text{start}(A_i) + \text{proc}(A_i) = \text{end}(A_i)\), \(E(A_i, t)\) is equal to \(c_i\) for every \(t\) in \([\text{start}(A_i), \text{end}(A_i)]\).

In the fully elastic case, the relation is even weaker because, even when \(t\) is known to belong to \(\text{set}(A_i)\), \(E(A_i, t)\) can take any value between 1 and \(C\).

### 10.1.2 Disjunctive Constraints

Disjunctive constraints deal with cases in which two activities cannot overlap in time. Such a situation is of course common in One-Machine scheduling, but also occurs in cumulative scheduling, when the sum of the capacities required by two activities exceeds the capacity of the resource. Let us note that the following rule, CNP-DISJ, can a priori be generalized to triples, quadruples, etc., of activities, but with a significant increase in the number of constraints and in the number of disjuncts per constraint. In practice, disjunctive constraints are used only for pairs of activities.

**CNP-DISJ:** Disjunctive constraints in the non-preemptive case

Let \(A_i\) and \(A_j\) be two activities with \(c_i + c_j > C\). In the non-preemptive case, the disjunctive constraint propagation technique consists of maintaining arc-B-consistency on the formula:

\[
[\text{end}(A_i) \leq \text{start}(A_j)] \lor [\text{end}(A_j) \leq \text{start}(A_i)]
\]

In the 1NP case, all the pairs of activities that require the same resource are related by such a disjunction. This is the origin of the term “disjunctive scheduling.”

**CP-DISJ:** Disjunctive constraints in the preemptive case

Let \(A_i\) and \(A_j\) be two activities with \(c_i + c_j > C\). In the preemptive case, the disjunctive constraint propagation technique consists of maintaining arc-B-consistency on the formula:

\[
\begin{align*}
[\text{start}(A_i) + \text{proc}(A_i) + \text{proc}(A_j) & \leq \text{end}(A_i)] \\
\lor [\text{start}(A_i) + \text{proc}(A_i) + \text{proc}(A_j) & \leq \text{end}(A_i)] \\
\lor [\text{start}(A_j) + \text{proc}(A_i) + \text{proc}(A_j) & \leq \text{end}(A_i)] \\
\lor [\text{start}(A_j) + \text{proc}(A_i) + \text{proc}(A_j) & \leq \text{end}(A_j)]
\end{align*}
\]
10.1.3 Edge-Finding

"Edge-Finding" constraint propagation techniques reason about the order in which activities execute on a given resource. In the 1NP case, Edge-Finding consists of determining whether a given activity \( A_i \) must execute before (or after) a given set of activities \( \Omega \). Cumulative and preemptive cases are more complex since several activities can overlap (on a cumulative resource) or preempt one another. Then Edge-Finding consists of determining whether an activity \( A_i \) must start or end before (or after) a set of activities \( \Omega \).

**1NP-EF**: Edge-Finding in the One-Machine non-preemptive case

Let \( A_i \ll A_j (A_i \gg A_j) \) mean that \( A_i \) is before (after) \( A_j \) and \( A_i \ll \Omega (A_i \gg \Omega) \) mean that \( A_i \) is before (after) all the activities in \( \Omega \). In the One-Machine non-preemptive case, the Edge-Finding technique consists in applying the following rules, and their symmetric counterparts:

\[
[A_i \notin \Omega] \land [\bar{d}_\Omega - r_{\Omega \cup\{A_i\}} < p_{\Omega \cup\{A_i\}}] \implies [A_i \gg \Omega]
\]

\[
[A_i \gg \Omega] \implies \left[ \text{start}(A_i) \geq \max_{\emptyset \neq \Omega' \subseteq \Omega} (r_{\Omega'} + p_{\Omega'}) \right]
\]

**1P-EF**: Edge-Finding in the One-Machine preemptive case

In the preemptive case, the Edge-Finding rules no longer order activities but start and end times of activities. If \( A_i \gg \Omega \) means "\( A_i \) ends after all activities in \( \Omega \)" then the following rules (and their symmetric counterparts) are obtained:

\[
[A_i \notin \Omega] \land [\bar{d}_\Omega - r_{\Omega \cup\{A_i\}} < p_{\Omega \cup\{A_i\}}] \implies [A_i \gg \Omega]
\]

\[
[A_i \gg \Omega] \implies \left[ \text{end}(A_i) \geq \max_{\emptyset \neq \Omega' \subseteq \Omega} (r_{\Omega' \cup\{A_i\}} + p_{\Omega' \cup\{A_i\}}) \right]
\]

\[
[A_i \gg \Omega] \land [\bar{d}_\Omega - r_\Omega = p_\Omega] \land [r_\Omega \leq r_i] \implies \left[ \text{start}(A_i) \geq \bar{d}_\Omega \right]
\]

In the “mixed” case with both interruptible and non-interruptible activities, the 1NP-EF rules can be applied whenever \( A_i \) is not interruptible, even if the activities in \( \Omega \) are interruptible (cf., Section 8.2). On the other hand, if \( A_i \) is interruptible, the 1NP-EF rules are not valid and the (weaker) 1P-EF rules must be applied.

**FE-EF**: Edge-Finding in the fully elastic case

The following rules (and their symmetric counterparts) can be used in the fully elastic case:

\[
[A_i \notin \Omega] \land \left[ C(\bar{d}_\Omega - r_{\Omega \cup\{A_i\}}) < e_{\Omega \cup\{A_i\}} \right] \implies [A_i \gg \Omega]
\]

\[
[A_i \gg \Omega] \implies \left[ \text{end}(A_i) \geq \max_{\emptyset \neq \Omega' \subseteq \Omega} \frac{Cr_{\Omega' \cup\{A_i\}} + e_{\Omega' \cup\{A_i\}}}{C} \right]
\]

\[
[A_i \gg \Omega] \land \left[ C(\bar{d}_\Omega - r_\Omega) = e_\Omega \right] \land [r_\Omega \leq r_i] \implies \left[ \text{start}(A_i) \geq \bar{d}_\Omega \right]
\]

Note that when applied in the CP and in the CNP cases, these rules are sensitive to the use of fake activities to represent intervals during which the resource capacity is \( C \) with \( 0 < c < C \) (because the fake activities are considered as fully elastic).

**CNP-EF1**: Edge-Finding in the cumulative non-preemptive case

Let \( \text{rest}(\Omega, c_i) = e_\Omega - (C - c_i)(\bar{d}_\Omega - r_\Omega) \). The following rules (and their symmetric counterparts) summarize Section 9.3.3.

\[
[A_i \notin \Omega] \land \left[ C(\bar{d}_\Omega - r_{\Omega \cup\{A_i\}}) < e_{\Omega \cup\{A_i\}} \right] \implies [A_i \gg \Omega]
\]

\[
[A_i \gg \Omega] \land [\emptyset \neq \Omega' \subseteq \Omega] \land [\text{rest}(\Omega', c_i) > 0] \implies \left[ \text{start}(A_i) \geq r_{\Omega'} + \frac{\text{rest}(\Omega', c_i)}{c_i} \right]
\]

**CNP-EF2**: Edge-Finding in the cumulative non-preemptive case
The following rules (and their symmetric counterparts) summarize Section 9.3.4.

\[
[A_i \notin \Omega] \land [r_i \leq r_\Omega < eet_i] \land [C(\tilde{d}_\Omega - r_\Omega) < c_\Omega + c_i(eet_i - r_\Omega)]
\Rightarrow [A_i > \Omega]
\]

\[
[A_i \neq \Omega] \land [0 \neq \Omega' \subseteq \Omega] \land [rest(\Omega', c_i) > 0]
\Rightarrow [start(A_i) \geq r_{\Omega'} + \frac{rest(\Omega', c_i)}{c_i}]
\]

10.1.4 Not-First, Not-Last

“Not-First” and “Not-Last” rules are counterparts to Edge-Finding rules. They deduce that an activity \( A_i \) cannot be the first (or the last) to execute in \( \Omega \cup \{ A_i \} \).

1NP-NFNL: One-Machine “Not-First” and “Not-Last” rules

The following rule (and its symmetric counterpart) can be applied in the One-Machine non-preemptive case:

\[
[A_i \notin \Omega] \land [\tilde{d}_\Omega - r_i < p_{R \cup \{A_i\}}] \Rightarrow [start(A_i) \geq eetmin_\Omega]
\]

CNP-NFNL: Cumulative “Not-First” and “Not-Last” rules

The following rule (and its symmetric counterparts) summarize Section 9.3.5.

\[
[A_i \neq \Omega] \land [r_\Omega \leq r_i < eetmin_\Omega] \land
[C(\tilde{d}_\Omega - r_\Omega) < c_\Omega + c_i(\min(eet_i, \tilde{d}_\Omega) - r_\Omega)]
\Rightarrow [start(A_i) \geq eetmin_\Omega]
\]

10.1.5 Energetic Reasoning

The Edge-Finding and the “Not-First” and “Not-Last” rules are such that the activities that do not belong to \( \Omega \) do not contribute to the analysis of the resource usage between \( r_{\Omega \cup \{A_i\}} \) and \( \tilde{d}_{\Omega \cup \{A_i\}} \). On the contrary, energetic reasoning rules compute the minimal contribution \( W(A_j, t_1, t_2) \) of each activity \( A_j \) to a given interval \( [t_1, t_2] \).

In the preemptive case, the required energy consumption of \( A_j \) over \( [t_1, t_2] \) is evaluated as follows:

\[
W_{pe}(A_j, t_1, t_2) = c_j \max(0, p_j - \max(0, t_1 - r_j) - \max(0, \tilde{d}_j - t_2))
\]

The notation \( W_{pe} \) introduced in Section 9.2.3 refers to the fact that this value corresponds to a particular relaxation of the cumulative resource constraint, identified as the “Partially Elastic” relaxation. In the non-preemptive case, a stronger value can be used:

\[
W_{Sh}(A_j, t_1, t_2) = c_j \min(t_2 - t_1, p_j^+(t_1), p_j^-(t_2))
\]

with \( p_j^+(t_1) = \max(0, p_j - \max(0, t_1 - r_j)) \) and \( p_j^-(t_2) = \max(0, p_j - \max(0, \tilde{d}_j - t_2)) \). The notation \( W_{Sh} \) refers to the fact that the best value is obtained by shifting the activity either to the left (i.e., to its earliest possible execution interval) or to the right (to its latest possible execution interval).

Many rules have been developed based on energetic reasoning (see, for example [19, 23, 29, 97, 159]). Only the most significant rules are recalled below. These rules are in practice applied only to some intervals \( [t_1, t_2] \) (cf., Section 9.3.6). For the theoretical comparison with other rules, it will be assumed that all intervals \( [t_1, t_2] \) are considered.

CP-ER: Energetic reasoning in the preemptive case

Let \( d^+(A_i, t_1, t_2) = \sum_{A_j \neq A_i} W_{pe}(A_j, t_1, t_2) + c_i p_i^+(t_1) - C(t_2 - t_1) \) and
Comparison of Propagation Techniques

CNP-ER-DISJ: Energetic reasoning in the non-preemptive case

This section summarizes the dominance relations under the following assumptions:

\[ d^-(A_i, t_1, t_2) = \sum_{A_j \neq A_i} W_{pe}(A_j, t_1, t_2) + c_i p_i (t_2 - t_1) - C(t_2 - t_1) \]

The following rules can be applied:

\[
\left[ \sum_{A_j} W_{pe}(A_j, t_1, t_2) - C(t_2 - t_1) > 0 \right] \Rightarrow contradiction
\]

\[
\left[ d^+(A_i, t_1, t_2) > 0 \right] \Rightarrow \left[ end(A_i) \geq t_2 + \frac{d^+(A_i, t_1, t_2)}{c_i} \right]
\]

\[
[t_1 \leq r_i] \land \left[ \sum_{A_j \neq A_i} W_{pe}(A_j, t_1, t_2) = C(t_2 - t_1) \right] \Rightarrow [start(A_i) \geq t_2]
\]

\[
[d^-(A_i, t_1, t_2) > 0 \right] \Rightarrow \left[ start(A_i) \leq t_1 - \frac{d^-(A_i, t_1, t_2)}{c_i} \right]
\]

\[
[d_i \leq t_2] \land \left[ \sum_{A_j \neq A_i} W_{pe}(A_j, t_1, t_2) = C(t_2 - t_1) \right] \Rightarrow [end(A_i) \leq t_1]
\]

CNP-ER: Energetic reasoning in the non-preemptive case

Let \( d^+(A_i, t_1, t_2) = \sum_{A_j \neq A_i} W_{Sh}(A_j, t_1, t_2) + c_i p_i^+ (t_1) - C(t_2 - t_1) \) and

\[
d^-(A_i, t_1, t_2) = \sum_{A_j \neq A_i} W_{Sh}(A_j, t_1, t_2) + c_i p_i^- (t_2) - C(t_2 - t_1) \]

The following rules can be applied:

\[
\left[ \sum_{A_j} W_{Sh}(A_j, t_1, t_2) - C(t_2 - t_1) > 0 \right] \Rightarrow contradiction
\]

\[
\left[ d^+(A_i, t_1, t_2) > 0 \right] \Rightarrow \left[ end(A_i) \geq t_2 + \frac{d^+(A_i, t_1, t_2)}{c_i} \right]
\]

\[
[t_1 \leq r_i] \land \left[ \sum_{A_j \neq A_i} W_{Sh}(A_j, t_1, t_2) = C(t_2 - t_1) \right] \Rightarrow [start(A_i) \geq t_2]
\]

\[
[d^-(A_i, t_1, t_2) > 0 \right] \Rightarrow \left[ start(A_i) \leq t_1 - \frac{d^-(A_i, t_1, t_2)}{c_i} \right]
\]

\[
[d_i \leq t_2] \land \left[ \sum_{A_j \neq A_i} W_{Sh}(A_j, t_1, t_2) = C(t_2 - t_1) \right] \Rightarrow [end(A_i) \leq t_1]
\]

CNP-ER-DISJ: Energetic reasoning in the non-preemptive case

\[
[t_1 = r_i] \land [t_2 = d_j] \land [t_1 < t_2] \land [c_i + c_j > C]
\]

\[
\land \left[ \sum_{A_k \notin \{A_i, A_j\}} W_{Sh}(A_k, t_1, t_2) + c_i p_i + c_j p_j > C(t_2 - t_1) \right]
\]

\[
\Rightarrow [end(A_j) \leq start(A_i)]
\]

10.2 Dominance Relations

This section summarizes the dominance relations under the following assumptions:

- The study considers only the deduction of new time-bounds (i.e., earliest and latest start and end times) from given time-bounds. When Time-Tables are used, other deductions are in fact performed, since the \( E(A_i, t) \) variables are updated. When several constraints refer to the same \( E(A_i, t) \) variables, this may lead to extra constraint propagation.
• In the CP, 1P, CNP and 1NP cases, we consider only the case in which the processing time and the resource capacity requirement of each activity are fixed. In the non-preemptive case, this assumption is particularly important because it implies that \( \text{start}(A_i) + p_i = \text{end}(A_i) \); hence any deduction concerning \( \text{start}(A_i) \) is equivalent to a deduction concerning \( \text{end}(A_i) \), and conversely.

• In the preemptive case, a peculiar “special effect” occurs when the \( \text{start}(A_i) \) variable is bound. Indeed, the value of this variable is then known to belong to \( \text{set}(A_i) \), an information which could theoretically be used in some constraint propagation rules (i.e., those based on Time-Tables). A similar effect occurs when the \( \text{end}(A_i) \) variable is bound. However, it appears that the use of this additional information would greatly impact the CPU time and memory space needed to update and exploit the Time-Tables. So, in practice, these “special effects” are ignored. To remain consistent with the actual practice, we also ignore these effects in the following comparisons.

• Extensions of the rules (e.g., to consider also setup times between activities [51, 103]) are ignored. Hence, some dominance relations may no longer hold when such extensions are considered.

Let us remark that the conditions of the CNP-EF2, CNP-NFNL and CNP-ER-DISJ rules are not monotonic (while FE-TT, CP-TT, CNP-TT, CP-DISJ, CNP-DISJ, FE-EF, 1P-EF, 1NP-EF, CNP-EF1, 1NP-NFNL, CP-ER and CNP-ER have monotonic conditions). This means that better time-bounds for some activities may prevent the application of the rule (and hence the drawing of the corresponding conclusion). For example, consider two non-interruptible activities with \( r_i = 7 \), \( d_i = 5 \), \( r_j = 1 \), \( d_j = 5 \), \( p_i = 3 \), \( p_j = 3 \), \( c_i = 1 \), \( c_j = 1 \) and \( C = 1 \). This example shows that CNP-EF2 is non-monotonic. Indeed, for \( X = 3 \), nothing is deduced, while for \( X = 0 \) or \( X = 1 \), the rule fires and finds \( \text{start}(A_i) = 4 \).

Dominance relations between non-monotonic rules are difficult to establish because the fact that a non-monotonic rule does not apply in a given state does not prove that it could not have been applied in a previous state. However, dominance relations between a monotonic rule \( R \) and a non-monotonic rule \( R' \) can be established without such worry.

Each of the FE, CP, 1P, CNP and 1NP cases is considered in turn. We note \( R \leq R_1 + R_2 + \ldots + R_n \) when the rule \( R \) is dominated by the conjunction of \( R_1, R_2, \ldots, R_n \) and \( R = R_1 + R_2 + \ldots + R_n \) when \( R \) and the conjunction of \( R_1, R_2, \ldots, R_n \) are equivalent. Similarly, we will use the notation \( R \not\leq R_1 + R_2 + \ldots + R_n \) when \( R \) is not dominated by the conjunction of \( R_1, R_2, \ldots, R_n \).

### 10.2.1 The Fully Elastic Case

**Proposition 63.** \( \text{FE-TT} \leq \text{FE-EF} \)

*Proof.* It is shown in Proposition 48 (Section 9.1) that FE-EF deduces the best possible bounds in the fully elastic case. Hence, FE-TT can never provide better bounds than FE-EF. \( \square \)

### 10.2.2 The Cumulative Preemptive Case

**Proposition 64.** \( \text{FE-TT} \leq \text{CP-TT} \)

*Proof.* Obvious. \( \square \)

**Proposition 65.** \( \text{FE-TT} \leq \text{FE-EF} \leq \text{CP-ER} \)

*Proof.* FE-TT \( \leq \) FE-EF is proven in Section 10.2.1. Let us now prove FE-EF \( \leq \) CP-ER.

FE-EF provides two types of conclusions. Let us first consider a conclusion of the first type, i.e., a new lower bound for \( \text{end}(A_i) \). It is shown in Section 9.1 that there exists a simple transformation of an instance of the Fully Elastic Problem into an instance of the One-Machine Preemptive Problem such that this conclusion corresponds to a conclusion of the 1P-EF rule on the transformed instance (Transformation 1). In addition, it is shown in [10] that if a set \( \Omega' \) provides the conclusion, then this
rule can be applied with $\Omega = \Omega'$ (to provide the same conclusion). This implies $d^+(A_i, t_1, t_2) > 0$ for $t_1 = r_{\Omega'}$ and $t_2 = d_{\Omega'}$. Then the CP-ER energetic rule deduces $end(A_i) \geq t_2 + d^+(A_i, t_1, t_2)/c_i$. Assuming $c_i \leq C$, this cannot be smaller than $t_1 + (e_{\Omega'} + c_ip_i(t_1))/C$, which in turn cannot be smaller than $r_{\Omega'}(A_i) + e_{\Omega'}(A_i)/C$. So the conclusion made by CP-ER is not weaker than the conclusion made by FE-EF.

Let us now consider a conclusion of the second type, i.e., a new lower bound for $start(A_i)$. The CP-ER rule obtains the same conclusion with $t_1 = r_\Omega$ and $t_2 = d_\Omega$. Hence FE-EF $\leq$ CP-ER.

10.2.3 The One-Machine Preemptive Case

Proposition 66.

$FE-TT = CP-TT \leq FE-EF = 1P-EF = CP-ER$

$CP-DISJ \leq FE-EF = 1P-EF = CP-ER$

Proof. When $C = 1$, any fully elastic schedule is a valid preemptive schedule, and conversely. This implies that FE-TT and CP-TT are equivalent and that FE-EF and 1P-EF are equivalent. In addition, 1P-EF is known to compute the best possible bounds. Hence 1P-EF dominates all the other rules. Since CP-ER dominates FE-EF (= 1P-EF), this implies that CP-ER, FE-EF and 1P-EF are equivalent and dominate all the other rules.

10.2.4 The Cumulative Non-Preemptive Case

Proposition 67. $FE-TT \leq FE-EF \leq CP-ER$

Proof. See Sections 10.2.1 and 10.2.2.

Proposition 68.

$FE-TT \leq CP-TT \leq CNP-TT$

$CP-DISJ \leq CNP-DISJ$

$CP-ER \leq CNP-ER$

Proof. Each of these relations is obvious when we assume that the activities have fixed processing times.

Proposition 69. $FE-EF \leq CNP-EF_1$

Proof. FE-EF provides two types of conclusions. Let us first consider a conclusion of the first type, i.e., a new lower bound for $end(A_i)$. The new lower bound is greater than $r_i + p_i$ and $d_\Omega$. It is shown in Transformation 1 that there exists a simple transformation of an instance of the Fully Elastic Problem into an instance of the One-Machine Preemptive Problem such that this conclusion corresponds to a conclusion of the 1P-EF rule on the transformed instance. In addition, it is shown in [10] that if a set $\Omega'$ provides the conclusion, then this rule can be applied with $\Omega = \Omega'$ (to provide the same conclusion). Then $rest(\Omega, c_i) > 0$, otherwise $c_i(\tilde{d}_\Omega - r_\Omega)$ units of energy could be allocated to $A_i$ between $r_\Omega$ and $\tilde{d}_\Omega$, which would not allow FE-EF to update the earliest end time of $A_i$. This implies that the condition of CNP-EF1 is satisfied for $\Omega = \Omega'$. Finally, the earliest end time of $A_i$ is updated to

$$r_\Omega + \frac{c\Omega - (C-c_i)(\tilde{d}_\Omega - r_\Omega)}{c_i} + p_i$$

Let us show that this conclusion is at least as good as the conclusion raised by FE-EF (provided that $c_i$ does not exceed $C$). We have:

$$C(\tilde{d}_\Omega - r_\Omega) \leq C(\tilde{d}_\Omega - r_{\Omega,\cup}(A_i)) < e_{\Omega,\cup}(A_i)$$

$$C(C-c_i)(d_\Omega - r_\Omega) \leq (C-c_i)e_{\Omega,\cup}(A_i)$$

$$c_i e_{\Omega,\cup}(A_i) \leq C e_{\Omega,\cup}(A_i) - C(C-c_i)(d_\Omega - r_\Omega)$$

Let us now consider a conclusion of the second type, i.e., a new lower bound for start(A). Then CNN-ER clearly obtains the same result for Ω = Ω′.

**Proposition 70.** CNN-ER ≤ CP-ER

**Proof.** Assume CNN-ER applies to the pair (A, Ω). CP-ER can be applied to A, t₁ = r_{Ω∪{A}} and t₂ = d_{Ω}. The result of this step is end(A) ≥ t₂ + d*(A,t₁,t₂)/c₁. This implies that, when CP-ER is applied, eetᵢ becomes strictly greater than t₂.

Let X denote the earliest start time provided by CNN-ER for a given subset Ω′. Let us now apply CP-ER to t₃ = r_{Ω′} and t₄ = d_{Ω′} as well as the processing time constraint start(A) + pᵢ = end(A), until we reach quiescence. Since CP-ER is monotonic, a unique xpoint can be reached in this manner. At this xpoint, either d*(A,t₃,t₄) ≤ 0 or eetᵢ ≥ t₄ + d*(A,t₃,t₄)/c₁.

This implies d*(A,t₃,t₄) ≤ max(0,cᵢ(eetᵢ - t₄)). Then, since t₄ ≤ t₂ < eetᵢ, this implies d*(A,t₃,t₄) ≤ cᵢ(eetᵢ - t₄).

However, d*(A,t₃,t₄) ≥ cᵢ + cᵢpᵢ⁺(t₃) - C(t₄ - t₃), which implies d*(A,t₃,t₄) > cᵢ(X - t₄ - 1 + pᵢ⁺(t₃)). This implies that at the xpoint we have (X - t₄ - 1 + pᵢ⁺(t₃)) < eetᵢ - t₄. Hence at the xpoint X + pᵢ⁺(t₃) ≤ eetᵢ. Since eetᵢ is strictly greater than t₄, pᵢ⁺(t₃) = pᵢ - max(0,t₃ - rᵢ).

Hence at the xpoint we have X - max(0,t₃ - rᵢ) ≤ rᵢ, which implies either X ≤ rᵢ or X ≤ t₄. But rest(X,cᵢ) > 0 implies X > t₄. Consequently, when the xpoint of CP-ER is reached, the obtained earliest start time rᵢ is at least as strong as X.

**Proposition 71.** CNN-ER ≤ CP-ER

**Proof.** Assume CNN-ER applies to the pair (A, Ω). Let t₁ = r_{Ω} and t₂ = d_{Ω}. We have d*(A,t₁,t₂) ≥ e_{Ω} + cᵢpᵢ⁺(t₁) - C(t₂ - t₁). Under the conditions of rule CNN-ER2, pᵢ⁺(t₁) = eetᵢ - t₁. Hence, d*(A,t₁,t₂) > 0 and CP-ER gives end(A) ≥ t₄ + d*(A,t₁,t₂)/c₁. This implies that, when CP-ER is applied, eetᵢ becomes strictly greater than t₂.

Let X denote the earliest start time provided by CNN-ER for a given subset Ω′. Let us now apply CP-ER to t₃ = r_{Ω′} and t₄ = d_{Ω′} as well as the processing time constraint start(A) + pᵢ = end(A), until we reach quiescence. Since CP-ER is monotonic, a unique xpoint can be reached in this manner. At this xpoint, either d*(A,t₃,t₄) ≤ 0 or eetᵢ ≥ t₄ + d*(A,t₃,t₄)/c₁.

This implies d*(A,t₃,t₄) ≤ max(0,cᵢ(eetᵢ - t₄)). Then, since t₄ ≤ t₂ < eetᵢ, this implies d*(A,t₃,t₄) ≤ cᵢ(eetᵢ - t₄).

However, d*(A,t₃,t₄) ≥ e_{Ω} + cᵢpᵢ⁺(t₃) - C(t₄ - t₃), which implies d*(A,t₃,t₄) > cᵢ(X - t₄ - 1 + pᵢ⁺(t₃)). This implies that at the xpoint we have (X - t₄ - 1 + pᵢ⁺(t₃)) < eetᵢ - t₄. Hence at the xpoint X + pᵢ⁺(t₃) ≤ eetᵢ. Since eetᵢ is strictly greater than t₄, pᵢ⁺(t₃) = pᵢ - max(0,t₃ - rᵢ).

Hence at the xpoint we have X - max(0,t₃ - rᵢ) ≤ rᵢ, which implies either X ≤ rᵢ or X ≤ t₄. But rest(X,cᵢ) > 0 implies X > t₄. Consequently, when the xpoint of CP-ER is reached, the obtained earliest start time rᵢ is at least as strong as X.

**Proposition 72.** CNN-TT ≤ CP-ER

**Proof.** Assume the application of CNN-TT results in an update of the earliest start and end times of Aᵢ. Let rᵢ and eetᵢ denote the initial earliest start and end times of Aᵢ. Since CNN-TT updates rᵢ and eetᵢ, there exists a time point t in [rᵢ, eetᵢ) such that \( \sum_{A_i \neq A} E(A_j, t) \) exceeds cᵢ.

For each Aᵢ with a non-null contribution in this sum, bτᵢ ≤ t < eetᵢ. This implies W_{bτ}(A_j, t, t + 1) = cᵢ. Hence, d*(A_j, t, t + 1) is equal to \( \sum_{A_i \neq A} E(A_j, t) + c_i (eet_i - t) - C > 0 \). Hence CNN-ER deduces end(A) ≥ t + 1 + (eetᵢ - t) + (\( \sum_{A_i \neq A} E(A_j, t) - C \))/cᵢ, which strictly exceeds the current value of eetᵢ. Consequently, when the applications of CNN-ER reach quiescence, the obtained earliest start and end times of Aᵢ are at least as good as those that are given by CNN-TT.
Remark: In this proof, we have applied CNP-ER to intervals of the form \([t,t+1]\). In fact, since \(E(A_j, t)\) is constant between \(\text{lst}_j, t, \text{eet}_j\) and since \(p_i^+(t_1) = \text{eet}_i - t_1\) for any \(t_1\) in \([r_i, \text{eet}_i]\), one can limit the application of CNP-ER to intervals \([t_1, t_2]\) of the form \([\text{lst}_j, \text{eet}_k]\) or \([r_i, \text{eet}_k]\) with \(A_j \not= A_i\) (and no constraint on \(A_k\)).

**Proposition 73. CP-TT \leq CP-ER**

*Proof.* Similar to the above, using the fact that an interruptible activity \(A_j\) contributes to the Time-Table if and only if \(\text{start}(A_j), \text{proc}(A_j)\) and \(\text{end}(A_j)\) are bound to values such that the relation \(\text{start}(A_j) + \text{proc}(A_j) = \text{end}(A_j)\) holds. \(\Box\)

### 10.2.5 The One-Machine Non-Preemptive Case

**Proposition 74.**

\[
\text{FE-TT} = \text{CP-TT} \leq \text{FE-EF} = 1\text{P-EF} = \text{CP-ER}
\]

\[
\text{CP-DISJ} \leq \text{FE-EF} = 1\text{P-EF} = \text{CP-ER}
\]

\[
\text{CNP-EF1} \leq \text{CP-ER} \leq \text{CNP-ER}
\]

\[
\text{CNP-EF2} \leq \text{CP-ER} \leq \text{CNP-ER}
\]

\[
\text{CNP-TT} \leq \text{CNP-ER}
\]

*Proof.* See Sections 10.2.3 and 10.2.4. \(\Box\)

**Proposition 75. CP-TT \leq CP-DISJ**

*Proof.* See Section 8.1.2

**Proposition 76.**

\[
\text{FE-TT} = \text{CP-TT} \leq \text{CNP-TT}
\]

\[
\text{CP-DISJ} \leq \text{CNP-DISJ} \leq \text{CNP-ER-DISJ}
\]

\[
\text{FE-EF} = 1\text{P-EF} < 1\text{NP-EF} = \text{CNP-EF1}
\]

\[
\text{CNP-DISJ} \leq 1\text{NP-NFNL}
\]

\[
\text{CNP-NFNL} \leq 1\text{NP-NFNL}
\]

*Proof.* Each of these relations is obvious when we assume that the activities have fixed processing times. \(\Box\)

**Proposition 77. FE-EF = 1P-EF = 1NP-EF = CNP-EF1 = CP-ER**

*Proof.* This follows from the previous dominance relations. An alternative proof of \(1\text{P-EF} = 1\text{NP-EF}\) (under the assumption that activities have fixed processing times) appears in Section 8.2.4. This proof shows that the difference between the two rules serves only to avoid repeated iterations of the algorithm. \(\Box\)

**Proposition 78. CNP-DISJ \leq CNP-ER**

*Proof.* Let’s assume that \(r_i, p_i, p_j > d_j\) and that the adjustment has some impact on \(r_i\) for instance, \(i.e., r_i < r_j + p_j\). Let us compute the value \(W_{Sh}(A_j, t_1, t_2)\) with \(t_1 = r_i\) and \(t_2 = r_i + p_i\).

\[
W_{Sh}(A_j, t_1, t_2) = \min(t_2 - t_1, p_i^+(t_1), p_j^-(t_2))
\]

\[
p_i^+(t_1) = \max(0, p_i - \max(0, t_1 - r_j))
\]

\[
p_j^-(t_2) = \max(0, p_j - \max(0, d_j - t_2))
\]

It is clear that each of the three terms \(t_2 - t_1, p_i^+(t_1)\) and \(p_j^-(t_2)\) is positive. Hence \(W_{Sh}(A_j, r_i, r_i + p_i) > 0\). So \(d^+(A_i, t_1, t_2) > 0\) and, therefore, \(\text{end}(A_i) > r_i + p_i\), which in turn leads to an improvement of at least 1 for \(r_i\). Since the same reasoning can be applied while \(r_i < r_j + p_j\), we are sure that after some application of the rule, we have \(r_i \geq r_j + p_j\) which corresponds to the adjustment computed by CNP-DISJ. \(\Box\)
The CP-ER rule and the CNP-ER rule deduce either that established by the following counterexamples are of interest in the non-preemptive cases CNP and end before second counterexamples are actually of interest in the non-preemptive cases, while the non-dominance relations CP, 1P, CNP and 1NP. The non-dominance relations that are established by the first and the second counterexamples are actually of interest in the non-preemptive cases CNP and 1NP.

This section provides a series of counterexamples with one machine and capacity requirements. For each example, each rule that performs some deduction is not dominated by the conjunction of the rules that perform no deduction. In particular, each rule that detects a contradiction (e.g., when the domain of some variable becomes empty) is not dominated by the conjunction of the rules that perform no deduction.

### 10.3.1 General Counterexamples

This section provides a series of counterexamples with one machine and \( \forall i, r_i + p_i = eet_i \wedge lst_i + p_i = d_i \). These counterexamples are fairly general as they apply in all the considered cases FE, CP, 1P, CNP and 1NP. The non-dominance relations that are established by the first and the second counterexamples are actually of interest in the five cases, while the non-dominance relations established by the following counterexamples are of interest in the non-preemptive cases CNP and 1NP.

**Counterexample A for FE, CP, 1P, CNP, 1NP**

\[
\begin{align*}
C &= 1 \\
p_i &= p_j = p_k = p_l = 1 \\
r_i &= r_j = r_k = r_l = 0 \\
eet_i &= eet_j = eet_k = eet_l = 1 \\
lst_i &= 100, lst_j = lst_k = lst_l = 2 \\
d_i &= 101, d_j = d_k = d_l = 3
\end{align*}
\]

Time-Table constraints and disjunctive constraints deduce nothing. All the Edge-Finding rules, the CP-ER rule and the CNP-ER rule deduce either that \( A_i \) cannot start before 3 or that \( A_i \) cannot end before 4. CNP-NFNL, 1NP-NFNL and CNP-ER-DISJ deduce only that \( A_i \) cannot start before 1. When \( r_i \) and \( eet_i \) are set to respectively 1 and 2, Time-Table constraints, disjunctive constraints,
CNP-NFNL, 1NP-NFNL and CNP-ER-DISJ make no additional deduction and CNP-EF2 no longer applies. Hence this counterexample shows:

- that Time-Tables and disjunctive constraints do not dominate any other technique;
- that CNP-NFNL, 1NP-NFNL and CNP-ER-DISJ (even with the help of Time-Tables and disjunctive constraints) do not dominate any of FE-EF, 1P-EF, 1NP-EF, CNP-EF1, CNP-EF2, CP-ER and CNP-ER;
- that the non-monotonic CNP-EF2 rule (even with the help of CNP-NFNL, 1NP-NFNL, CNP-ER-DISJ, Time-Tables and disjunctive constraints) does not dominate any of FE-EF, 1P-EF, 1NP-EF, CNP-EF1, CP-ER and CNP-ER.

**Counterexample B for FE, CP, 1P, CNP, 1NP**

\[
\begin{align*}
C &= 1 \\
p_i &= 10, p_j = 1 \\
r_i &= r_j = 0 \\
et_{i} &= 10, net_{j} = 1 \\
let_{i} &= 10, let_{j} = 9 \\
d_i &= 20, d_j = 10
\end{align*}
\]

The Time-Table propagation rules FE-TT, CP-TT and CNP-TT deduce nothing. All the other rules deduce either that \( A_i \) cannot start before 1 or that \( A_i \) cannot end before 11. Hence, the Time-Table propagation rules never dominate any other rule.

**Counterexample C for CNP, 1NP**

\[
\begin{align*}
C &= 1 \\
p_i &= p_j = 5 \\
r_i &= r_j = 0 \\
et_{i} &= 6, net_{j} = 5 \\
let_{i} &= 95, let_{j} = 0 \\
d_i &= 100, d_j = 5
\end{align*}
\]

All propagation rules deduce \( start(A_i) \geq 5 \) or \( end(A_i) \geq 10 \) except CNP-EF2 which is blocked by the condition \( r_i \leq r_\Omega \). This proves that CNP-EF2 dominates no other rule.

**Counterexample D for CNP, 1NP**

\[
\begin{align*}
C &= 1 \\
p_i &= 11, p_j = 10 \\
r_i &= 0, r_j = 10 \\
et_{i} &= 11, net_{j} = 20 \\
let_{i} &= 30, let_{j} = 10 \\
d_i &= 41, d_j = 20
\end{align*}
\]

The CNP-NFNL rule deduces nothing while all the other rules deduce either that \( A_i \) cannot start before 20 or that \( A_i \) cannot end before 21. Let us remark that CNP-NFNL does not apply only because the condition \( r_\Omega \leq r_i \) is not satisfied.
Counterexample E for CNP, 1NP

\begin{align*}
  C &= 1 \\
  p_i &= p_j = 2, p_k = 1 \\
  r_i &= r_j = 0, r_k = 1 \\
  eet_i &= eet_j = 2, eet_k = 2 \\
  lst_i &= lst_j = 3, lst_k = 99 \\
  \bar{d}_i &= \bar{d}_j = 5, \bar{d}_k = 100
\end{align*}

This example shows that the “Not-First” and “Not-Last” rules are not dominated by the conjunction of all other rules. Indeed, 1NP-NFNL and CNP-NFNL deduce that \( A_k \) cannot start before 2 while all the other rules deduce nothing.

Counterexample F for CNP, 1NP

\begin{align*}
  C &= 1 \\
  p_i &= 3, p_j = 2 \\
  r_i &= 0, r_j = 2 \\
  eet_i &= 3, eet_j = 4 \\
  lst_i &= 2, lst_j = 98 \\
  \bar{d}_i &= 5, \bar{d}_j = 100
\end{align*}

The rules CNP-TT, CNP-ER, CNP-ER-DISJ, CNP-DISJ, 1NP-NFNL and CNP-NFNL deduce that \( A_j \) cannot start before 3 while all other rules deduce nothing.

Counterexample G for CNP, 1NP

\begin{align*}
  C &= 1 \\
  p_i &= 3, p_j = 1, p_k = 3, p_l = 3 \\
  r_i &= 2, r_j = 2, r_k = 0, r_l = 1 \\
  eet_i &= 5, eet_j = 3, eet_k = 3, eet_l = 4 \\
  lst_i &= 97, lst_j = 8, lst_k = 8, lst_l = 6 \\
  \bar{d}_i &= 100, \bar{d}_j = 9, \bar{d}_k = 11, \bar{d}_l = 9
\end{align*}

The CNP-ER-DISJ rule deduces \( \text{start}(A_i) \geq 4 \). The 1NP-NFNL and CNP-NFNL rules deduce \( \text{start}(A_i) \geq 3 \). The other rules deduce nothing. The reader can verify than when \( r_i \) is set to 3, none of the fifteen rules apply. Even CNP-ER-DISJ cannot deduce \( \text{start}(A_i) \geq 4 \) when \( r_i = 3 \). This illustrates the non-monotonic behavior of CNP-ER-DISJ.
10.3.2 A One-Machine Preemptive Counterexample

Counterexample H for CP, 1P

\[ C = 1 \]
\[ p_i = p_j = 1, p_k = 6 \]
\[ r_i = 2, r_j = 5, r_k = 0 \]
\[ eet_i = 3, eet_j = 6, eet_k = 7 \]
\[ lst_i = 2, lst_j = 5, lst_k = 1 \]
\[ \tilde{d}_i = 3, \tilde{d}_j = 6, \tilde{d}_k = 8 \]

This example applies only in the preemptive case since \( eet_k \) is not equal to \( r_k + p_k \). All the preemptive rules deduce that \( A_k \) cannot end before 8, except CP-DISJ, which deduces nothing.

10.3.3 Cumulative Counterexamples

Counterexample I for CP, CNP

\[ C = 2 \]
\[ c_i = c_j = c_k = 1 \]
\[ p_i = p_j = p_k = 1 \]
\[ r_i = r_j = r_k = 0 \]
\[ eet_i = eet_j = eet_k = 1 \]
\[ lst_i = lst_j = lst_k = 0 \]
\[ \tilde{d}_i = \tilde{d}_j = \tilde{d}_k = 1 \]

This example shows that, in the cumulative case, the disjunctive constraints CP-DISJ, CNP-DISJ and CNP-ER-DISJ cannot be used alone. Indeed, all the variables are instantiated, the resource constraint is violated, and these rules do not apply. All the other cumulative constraint propagation rules detect the contradiction.

Remark: The generalization of CNP-DISJ to triples of activities with \( c_i + c_j + c_k > C \) (cf., Section 10.1.2) also enables the detection of the contradiction.

Counterexample J for CP, CNP

\[ C = 5 \]
\[ c_i = c_j = c_k = 2 \]
\[ p_i = p_j = 2, p_k = 8 \]
\[ r_i = r_j = 3, r_k = 0 \]
\[ eet_i = eet_j = 5, eet_k = 8 \]
\[ lst_i = lst_j = 3, lst_k = 0 \]
\[ \tilde{d}_i = \tilde{d}_j = \tilde{d}_k = 8 \]

This example shows that, in the cumulative case, the disjunctive constraints CP-DISJ, CNP-DISJ and CNP-ER-DISJ, the Edge-Finding rules FE-EF and CNP-EF1, and the “Not-First, Not-Last” rules CNP-NFNL cannot be used alone. Indeed, all the variables are instantiated, the resource
constraint is violated, and these rules do not apply. All the other cumulative constraint propagation rules, except FE-TT, detect the contradiction.

Remark: The generalization of CNP-DISJ to triples of activities with \( c_i + c_j + c_k > C \) (cf., Section 10.1.2) also enables the detection of the contradiction.

**Counterexample K for CP, CNP**

\[
C = 6
\]
\[
c_i = 2, c_j = 5
\]
\[
p_i = 6, p_j = 4
\]
\[
r_i = 2, r_j = 0
\]
\[
eet_i = 8, eet_j = 4
\]
\[
lst_i = 94, lst_j = 5
\]
\[
d_i = 100, d_j = 9
\]

The CP-DISJ and the CNP-DISJ rules deduce either that \( \text{start}(A_i) \geq 4 \) or that \( \text{end}(A_i) \geq 10 \) while all the other rules deduce nothing. This shows that in the cumulative case, the disjunctive rules are not dominated by any of the other rules. This results from the fact that the disjunctive rules apply even when \( c_i + c_j \) is just a little greater than \( C \).

**Counterexample L for FE, CP, CNP**

\[
C = 5
\]
\[
c_i = c_j = c_k = 2
\]
\[
p_i = 22, p_j = p_k = 24
\]
\[
r_i = r_j = r_k = 0
\]
\[
eet_i = 22, eet_j = eet_k = 24
\]
\[
lst_i = 78, lst_j = lst_k = 2
\]
\[
d_i = 100, d_j = d_k = 26
\]

FE-TT, CP-TT, CP-DISJ, CNP-DISJ, CNP-ER-DISJ deduce nothing. CNP-TT and CNP-NFNL both deduce that \( A_i \) cannot start before 24. CNP-EF1 and CNP-EF2 deduce only that \( A_i \) cannot start before 9.

FE-EF deduces that \( A_i \) cannot end before 28. In the FE and CP cases, this does not relaunch any propagation, even if FE-TT, CP-TT and CP-DISJ are active. In the non-preemptive case, this implies that \( A_i \) cannot start before 6. Then FE-EF stops.

CP-ER with \( t_1 = 0 \) and \( t_2 = 26 \) provides \( \text{end}(A_i) \geq 26 + (96 + 44 - 130)/2 = 31 \). In the non-preemptive case, this implies \( \text{start}(A_i) \geq 9 \). Then CP-ER enters in a series of iterations:

- CP-ER with \( t_1 = 9 \) and \( t_2 = 26 \) provides \( \text{end}(A_i) \geq 26 + (60 + 44 - 85)/2 \), hence \( \text{end}(A_i) \geq 36 \), which in the non-preemptive case implies \( \text{start}(A_i) \geq 14 \).
- Then CP-ER with \( t_1 = 14 \) and \( t_2 = 26 \) provides \( \text{end}(A_i) \geq 26 + (40 + 44 - 60)/2 = 38 \), which in the non-preemptive case implies \( \text{start}(A_i) \geq 16 \).
- Then CP-ER with \( t_1 = 16 \) and \( t_2 = 26 \) provides \( \text{end}(A_i) \geq 26 + (32 + 44 - 50)/2 = 39 \), which in the non-preemptive case implies \( \text{start}(A_i) \geq 17 \).
- Then CP-ER with \( t_1 = 17 \) and \( t_2 = 26 \) provides \( \text{end}(A_i) \geq 26 + (28 + 44 - 45)/2 \), hence \( \text{end}(A_i) \geq 40 \), which in the non-preemptive case implies \( \text{start}(A_i) \geq 18 \).
- Then CP-ER stops with this result. It can be seen that there exists a partially elastic schedule of \( A_j \) and \( A_k \) that enables \( A_i \) to execute between 18 and 40.
Similarly, CNP-ER enters in a series of iterations:

- CNP-ER with \( t_1 = 2 \) and \( t_2 = 24 \) provides \( \text{end}(A_i) \geq 24 + (88 + 40 - 110)/2 = 33 \), which implies \( \text{start}(A_i) \geq 11 \).

- Then CNP-ER with \( t_1 = 11 \) and \( t_2 = 24 \) provides \( \text{end}(A_i) \geq 24 + (52 + 44 - 65)/2 = 43 \), which implies \( \text{start}(A_i) \geq 21 \).

- Then CNP-ER with \( t_1 = 18 \) and \( t_2 = 24 \) provides \( \text{end}(A_i) \geq 24 + (4 + 44 - 5)/2 = 43 \), which implies \( \text{start}(A_i) \geq 24 \).

Hence, in the preemptive case, FE-EF is not dominated by CP-TT + CP-DISJ and CP-ER is not dominated by FE-EF + CP-TT + CP-DISJ.

In the non-preemptive case, only CNP-TT, CNP-NFNL and CNP-ER deduce \( \text{start}(A_i) \geq 24 \). CP-ER deduces \( \text{start}(A_i) \geq 18 \). CNP-EF1 and CNP-EF2 deduce \( \text{start}(A_i) \geq 9 \) and FE-EF deduces \( \text{start}(A_i) \geq 6 \).

**Counterexample M for CP**

\[
C = 3 \\
e_i = 2, c_j = c_k = 1 \\
p_i = 2, p_j = p_k = 4 \\
r_i = 0, r_j = r_k = 1 \\
eet_i = 3, eet_j = eet_k = 5 \\
lst_i = 3, lst_j = lst_k = 1 \\
d_i = 6, d_j = d_k = 5
\]

CP-TT deduces that \( A_i \) must start at time 0 and end at time 6, while FE-TT, FE-EF, CP-ER and CP-DISJ deduce nothing.

### 10.4 Summary

This section summarizes the results of the previous sections. Each of the FE, CP, 1P, CNP and 1NP cases is considered in turn.

#### 10.4.1 The Fully Elastic Case

The FE-EF rule strictly dominates the FE-TT rule (cf., section 10.2.1 and counterexamples A, B and L).

Let us remark, however, that the FE-TT rule is not really dominated if the same \( E(A_i, t) \) variables appear in several constraints.

#### 10.4.2 The Cumulative Preemptive Case

In the cumulative preemptive case, we have the following results:

- FE-TT \( \leq \) FE-EF \( \leq \) CP-ER
- FE-TT \( \leq \) CP-TT
• CP-ER $\not\leq$ FE-EF + CP-TT + CP-DISJ (counterexample L)
• CP-TT $\not\leq$ CP-ER + CP-DISJ (counterexample M)
• CP-DISJ $\not\leq$ CP-ER + CP-TT (counterexample K)
• FE-EF $\not\leq$ CP-TT + CP-DISJ (counterexample A)
• FE-TT $\not\leq$ CP-DISJ (counterexample H)

10.4.3 The One-Machine Preemptive Case

In the One-Machine preemptive case, we have the following results:

• FE-TT = CP-TT
• FE-EF = CP-ER = 1P-EF
• CP-TT $\leq$ 1P-EF
• CP-DISJ $\leq$ 1P-EF
• 1P-EF $\not\leq$ CP-TT + CP-DISJ (counterexample A)
• CP-DISJ $\not\leq$ CP-TT (counterexample B)
• CP-TT $\not\leq$ CP-DISJ (counterexample H)

10.4.4 The Cumulative Non-Preemptive Case

The following results hold:

• FE-TT $\leq$ CP-TT $\leq$ CNP-TT $\leq$ CNP-ER
• FE-TT $\leq$ FE-EF $\leq$ CNP-EF1 $\leq$ CP-ER $\leq$ CNP-ER
• CNP-EF2 $\leq$ CP-ER $\leq$ CNP-ER
• CP-DISJ $\leq$ CNP-DISJ
• CP-TT $\leq$ CP-ER

Many non-dominance relations have been proven in Section 10.3. In particular no other binary relation, comparing one rule with another, holds.

10.4.5 The One-Machine Non-Preemptive Case

The following results hold:

• FE-TT = CP-TT
• FE-EF = 1NP-EF = 1P-EF = CNP-EF1 = CP-ER
• CP-TT $\leq$ CNP-TT $\leq$ CNP-DISJ $\leq$ 1NP-NFNL

As in the cumulative non-preemptive case, many non-dominance relations have been proven in Section 10.3. In particular no other binary relation, comparing one rule with another, holds.

The following tables summarize the results. For each couple of rules \( R_1 \) and \( R_2 \), the entry at row \( R_1 \) and column \( R_2 \) indicates whether \( R_1 \) dominates \( R_2 \). If \( R_1 \) dominates \( R_2 \), the entry is “Yes”; otherwise, a list of counterexamples showing that \( R_2 \) is not dominated by \( R_1 \) is provided.

Table 10.5: Comparison in the 1NP case. Does $\mathcal{R}_1$ dominate $\mathcal{R}_2$?
Chapter 11

Propagation of Objective Functions

In our model, a variable criterion represents the value taken by the objective function.

\[ \text{criterion} = F(\text{end}(A_1), \ldots, \text{end}(A_n)) \] (11.1)

Considering the objective constraint and the resource constraints independently is not a problem when \( F \) is a “maximum” such as \( C_{\text{max}} \) or \( T_{\text{max}} \). Indeed, the upper bound on criterion is directly propagated on the completion time of each activity, i.e., deadlines are efficiently tightened. The situation is much more complex for sum functions such as \( \sum w_i C_i, \sum w_i T_i \) or \( \sum w_i U_i \). For these functions, the constraint (11.1) has to be taken into account at each step of the search tree. An efficient constraint propagation technique must consider the resource constraints and the objective constraint simultaneously. In the following sections, we study three objective functions: \( \sum w_i U_i \), \( \sum T_i \) and the minimization of setup times.

In all cases, we restrict our study to the situation where each activity requires one machine among a set of \( m \) parallel identical machines. So we assume that the resource capacity is \( \text{cap}(R) = C = m. \)

For total tardiness, we are even more restrictive since we only consider the situation where \( m = 1 \).

11.1 Total Weighted Number of Late Activities

As far as the \( \sum w_i U_i \) objective function is concerned, our resource constraint is strongly related to the classical problem \( P|r_i| \sum w_i U_i \). However, in the classical problem, a late job can be scheduled arbitrary late, while in our model a late activity still has to execute before its deadline.

Many researchers have worked on special cases of \( P|r_i| \sum w_i U_i \). We first review the known complexity results under several assumptions, (e.g., one machine vs. \( m \) machines, preemption vs. non-preemption, equal processing times vs. arbitrary processing times, equal release dates vs. arbitrary release dates, equal weights vs. arbitrary weights). There are few results for the problem where the number of machines is unknown and most results apply for \( Pm|r_i| \sum w_i U_i \). Without loss of generality, we can suppose in \( P|r_i| \sum w_i U_i \) that \( r_i + p_i = d_i \), for all \( i \), since otherwise \( J_i \) cannot be done on time.

11.1.1 Complexity Results

Unit or Equal Processing Times

When \( \forall i, p_i = p \), most of the problems become polynomially solvable. We refer to Chapters 2 and 3 for a detailed study of these problems.
Unweighted Case

The simple problem $1|| \sum w_i U_i$ is already NP-hard. However, it can be solved in pseudo-polynomial time by dynamic programming [145]. The same result also applies for any fixed number of machines $Pm|| \sum w_i U_i$ [144].

Preemption

On a single machine, relaxing non-preemption is only of interest if release dates are distinct (otherwise preemptive schedules can be transformed into non-preemptive ones by rescheduling jobs in non-increasing order of their completion times). Lawler [142] has proposed a pseudo-polynomial algorithm for the Preemptive One-Machine Problem with weights $1|r_i, pmtn| \sum w_i U_i$. Time and space bounds of this algorithm are respectively $O(n^3W^2)$ and $O(n^2W)$, where $W$ is the sum of the weights of the jobs. The time and space bounds of Lawler’s algorithm have been improved in [14] for the unweighted case, to respectively $O(n^4)$ and $O(n^5)$. Allowing preemption on parallel machines does not make the problem easier since Du and others have shown that $P2|pmtn, r_j| \sum U_j$ is NP-hard [92].

Table 11.1: Complexity results

11.1.2 A Lower Bound of the Number of Late Activities

Obtaining a good lower bound of the weighted number of late activities is the first step of the constraint propagation process. This lower bound is also a lower bound for the domain of the variable criterion. Relaxing non-preemption is a well-known technique to obtain good lower bounds. Unfortunately, the preemptive problems remain difficult (cf., Table 11.1) except for $m = 1$ and equal weights. In such a case, the best available algorithm still runs in $O(n^4)$ and it is hardly usable in practice (cf., the computational tests performed in [14]). A “relaxed preemptive lower bound”, i.e., a slightly stronger relaxation than the preemptive relaxation, can be used. As shown below, it can...
be computed in \(O(n^2 \log n)\) and is valid for all type of resource constraints (either with one or several machines).

First, recall that the fully elastic relaxation (Section 9.1) transforms a cumulative resource constraint into a preemptive One-Machine constraint. From now on, we study the Preemptive One-Machine Problem with weights. The lower bounds and the deductions made on this latter resource constraint will be immediately applied on the initial problem (e.g., if there are 3 late activities on the preemptive One-Machine schedule, there are at least 3 late activities on the cumulative problem; if the earliest start time of the activity \(A_i\) is adjusted to \(x\) on the preemptive problem, the corresponding adjustment will be \(\left\lceil \frac{x}{m} \right\rceil\)).

Let us recall some well-known results on the One-Machine Problem. Its preemptive relaxation is polynomial and has some very interesting properties:

- There exists a feasible preemptive schedule if and only if over any interval \([t_1, t_2]\), the sum of the processing times of the activities in \(\{A_i : [t_1 \leq r_i] \land [\bar{d}_i \leq t_2]\}\) is lower than or equal to \(t_2 - t_1\). It is well known that relevant values for \(t_1\) and \(t_2\) are respectively the release dates and the deadlines [55].

- Jackson’s Preemptive Schedule (JPS) is feasible (i.e., each activity ends before its deadline) if and only if there exists a feasible preemptive schedule.

Now assume that JPS is feasible. Proposition 80 highlights the structure of the time intervals \([t_1, t_2]\) that are full on JPS, i.e., such that

\[
\sum_{A_i} p_i = t_2 - t_1
\]

**Proposition 80.** If two overlapping intervals are full, their intersection is full.

**Proof.** Let \([\tau_1, \tau_2]\) and \([\theta_1, \theta_2]\) be such intervals and let us assume, without any loss of generality that \(\theta_1 \leq \tau_1\) (cf., Figure 11.1). If \(\tau_2 < \theta_2\), the lemma obviously holds. Assume then that \(\tau_2 \geq \theta_2\). Notice that

\[
\{A_i : \theta_1 \leq r_i \land \bar{d}_i \leq \theta_2\} \subseteq \{A_i : \theta_1 \leq r_i \land \bar{d}_i \leq \tau_2\}
\]

\[
\{A_i : \tau_1 \leq r_i \land \bar{d}_i \leq \tau_2\} \subseteq \{A_i : \tau_1 \leq r_i \land \bar{d}_i \leq \tau_2\}
\]

Hence, the load of the machine over \([\theta_1, \tau_2]\) is

\[
\sum_{\theta_1 \leq r_i} p_i \geq \sum_{\theta_1 \leq r_i} p_i + \sum_{\tau_1 \leq r_i} p_i - \sum_{\tau_1 \leq r_i} p_i
\]

Since the load of the machine over \([\theta_1, \tau_2]\) is not greater than \(\tau_2 - \theta_1\) and since the loads over \([\tau_1, \tau_2]\) and \([\theta_1, \theta_2]\) are respectively \(\tau_2 - \tau_1\) and \(\theta_2 - \theta_1\),

\[
\sum_{\tau_1 \leq r_i} p_i \geq \theta_2 - \theta_1 + \tau_2 - \tau_1 - (\tau_2 - \theta_1) \geq \theta_2 - \tau_1
\]

Consequently, the intersection is also full. \(\square\)

We introduce a decision variable \(x_i\) per activity that equals 1 when the activity is on-time and 0 otherwise. Notice that if \(\bar{d}_i \leq d_i\), \(A_i\) is on-time in any solution, i.e., \(x_i = 1\). In such a case we adjust the value of \(d_i\) to \(\bar{d}_i\) (this has no impact on solutions) so that due dates are always smaller than or
equal to deadlines. We also assume that there is a preemptive schedule that meets all deadlines (if not, the resource constraint does not hold and a backtrack occurs). The following Mixed Integer Program (MIP) computes the minimum weighted number of late activities in the preemptive case:

\[
\begin{aligned}
\min & \sum_{i=1}^{n} w_i (1 - x_i) \\
\text{u.c.} & \forall t_1, \forall t_2 > t_1, \sum_{S(t_1,t_2)} p_i + \sum_{P(t_1,t_2)} p_i x_i \leq t_2 - t_1
\end{aligned}
\]

(11.2)

where \(S(t_1,t_2)\) is the set of activities that are sure to execute between \(t_1\) and \(t_2\) and where \(P(t_1,t_2)\) is the set of activities that are preferred to execute between \(t_1\) and \(t_2\).

\[
\begin{aligned}
S(t_1,t_2) &= \{ A_i : r_i \geq t_1 \land d_i \leq t_2 \} \\
P(t_1,t_2) &= \{ A_i : r_i \geq t_1 \land d_i > t_2 \land d_i \leq t_2 \}
\end{aligned}
\]

Actually, it easy to see that the relevant values of \(t_1\) and \(t_2\) correspond respectively to

- the release dates,
- the due dates and the deadlines.

Hence, there are \(O(n^2)\) constraints in the MIP. In the following, the notation \((t_1,t_2)\) refers to the resource constraint over the interval \([t_1,t_2)\). We now focus on the continuous relaxation of (11.2) in which the following constraints are added: For any activity \(A_i\) such that \(r_i + p_i > d_i\), i.e., for any late activity, \(x_i = 0\).

\[
\begin{aligned}
\min & \sum_{i=1}^{n} w_i (1 - x_i) \\
\text{u.c.} & \forall t_1 \in \{r_i\}, \forall t_2 \in \{\tilde{d}_i\} \cup \{d_i\} \quad (t_2 > t_1) \\
& \sum_{S(t_1,t_2)} p_i + \sum_{P(t_1,t_2)} p_i x_i \leq t_2 - t_1
\end{aligned}
\]

(11.3)

(11.3) can be solved in \(O(n^2 \log n)\) steps. To achieve this result, we first provide a characterization of a vector that realizes the optimum. From now on, suppose that activities are sorted in non-increasing order of \(w_i/p_i\) (this value corresponds to a cost per unit). We introduce the notion of well-structured instances. As we will see later on, (11.3) can be solved very efficiently for well-structured instances. Instances that are not well-structured are modified to become well-structured.

**Definition 29.** An instance is well-structured if and only if for any pair of activities \(A_i\) and \(A_j\) with \(i < j\),

\[
\begin{aligned}
& d_i < \tilde{d}_j \\
& d_j < \tilde{d}_i \Rightarrow \tilde{d}_i \leq \tilde{d}_j
\end{aligned}
\]
Proposition 81. For any well-structured instance, the largest vector (according to the lexicographical order) satisfying all the constraints of (11.3) realizes the optimum of (11.3).

Proof. Let $Y = (Y_1, \ldots, Y_n)$ be the largest vector (according to the lexicographical order) satisfying all the constraints of (11.3), i.e., $Y_1$ is maximal, $Y_2$ is maximal (given $Y_1$), $Y_3$ is maximal (given $Y_1$ and $Y_2$), \ldots, $Y_n$ is maximal (given $Y_1, \ldots, Y_{n-1}$). Moreover, let $X = (X_1, \ldots, X_n)$ be the largest (according to the lexicographical order) optimal vector of (11.3). Suppose that $X \neq Y$; let then $u$ be the first index such that $X_u < Y_u$. Consider the set $K$ of constraints that are saturated at $X$.

$$K = \{(t_1, t_2) : A_u \in P(t_1, t_2) \land \sum_{S(t_1, t_2)} p_i + \sum_{P(t_1, t_2)} p_iX_i = t_2 - t_1\}$$

If $K$ is empty, then none of the constraints containing the variable $X_u$ is saturated at the point $X$. $X_u < Y_u$ ensures that $X_u < 1$ and that $x_u$ is not constrained to be equal to 0 due to the second set of constraints; thus, $X$ is not an optimum of (11.3). Hence $K$ is not empty. Let then $(\tau_1, \tau_2) \in K$ be the pair such that $\tau_1$ is maximum and $\tau_2$ is minimum (given $\tau_1$). Let $(\theta_1, \theta_2) \in K$ be the pair such that $\theta_2$ is minimum and $\theta_1$ is maximum (given $\theta_2$).

Suppose that $\theta_1 < \tau_1$. Since $A_u \notin P(\tau_1, \tau_2)$ and $A_u \notin P(\theta_1, \theta_2)$, we have $\theta_1 < \tau_1 \leq r_u \leq \tilde{d}_u \leq \theta_2 < \tau_2$. We claim that the constraint $(\tau_1, \theta_2)$ is also saturated. To prove our claim, we introduce for each activity $A_i$ two fictive activities $A_i'$ and $A_i''$. They have the same earliest start time $r_i' = r_{i+1} = r_i$, their processing times are respectively $p_i' = p_iX_i$ and $p_i'' = p_i(1 - X_i)$, their latest end times are respectively $d_i' = d_i$ and $d_i'' = d_i$. If $A_i$ is on-time, it corresponds to the fictive activity $A_i'$ and otherwise to $A_i''$. The constraints of (11.3) hold, hence there is a preemptive schedule of these activities. On top of that, the time intervals $[\tau_1, \theta_2]$ and $[\theta_1, \theta_2]$ are full. These intervals overlap in time thus, according to Proposition 80, the interval $[\tau_1, \theta_2]$ is full: which leads $(\tau_1, \theta_2) \in K$ for the initial problem. This, together with $\theta_1 < \tau_1$ contradicts our hypothesis on the choice of $\theta_2$.

Now suppose that $\theta_1 = \tau_1 = t_1$ and $\theta_2 = \tau_2 = t_2$. The pair $(t_1, t_2)$ is the unique minimal saturated constraint containing the variable $x_u$. We claim that among activities in $P(t_1, t_2)$, there is one, say $A_v$, such that $v > u$ and $X_v > 0$ (otherwise we could prove, because $X_u < Y_u$, that $X_u$ can be increased; which contradicts the fact that $X$ is optimal). Consider now $X'$ the vector defined as follows: for $i \notin \{u, v\}$, $X_i' = X_i$ and $X_v' = X_v + \epsilon/p_v$ and $X_u' = X_u - \epsilon/p_v$, where $\epsilon > 0$ is a small value such that $\epsilon \leq p_v(1 - X_u)$, $\epsilon \leq p_vX_v$ and such that for any non-saturated constraint $(t_1', t_2')$,

$$\epsilon + \sum_{S(t_1', t_2')} p_i + \sum_{P(t_1', t_2')} p_iX_i \leq t_2' - t_1'$$

First recall that activities are sorted, hence $\epsilon w_u/p_u - \epsilon w_v/p_v \geq 0$. Thus, $\sum w_i(1 - X_i') \leq \sum w_i(1 - X_i)$. Moreover, $X'$ is “better” for the lexicographical order than $X$. Second, because of the definition of $\epsilon$, the constraints that were not saturated for $X$ are not violated for $X'$. Third we claim that the saturated constraints in $K$ (for the vector $X'$) that contain the variables $x_u$ also contain $x_v$. Indeed, because $A_u$ and $A_v$ both belong to $P(t_1, t_2)$, we have $d_u < d_v$ and $d_v < d_u$. On top of that, $u < v$ thus, because the instance is well-structured, we have $\tilde{d}_u \leq \tilde{d}_v$. Hence, a saturated constraint that contains $x_u$ (and hence include the interval $[t_1, t_2]$) also contains $x_v$. As a consequence $X'$ meets all constraints. This contradicts our hypothesis on $X$. \qed

Proposition 81 induces a simple algorithm (Algorithm 17) to compute the optimum $X$ of (11.3). Each time, we compute the maximum resource constraint violation if the activity is fully on-time (lines 6–18). Given this violation, the maximum value $X_i$ that the variable $x_i$ can take is computed. This algorithm runs in $O(n^2)$ since there are $n$ activities $A_i$ and since for each of them $O(n^2)$ violations are computed, each of them in linear time.

Algorithm 18 makes the same computation as Algorithm 17 but uses JPS to compute the violation. The procedure “ComputeJPS” of Algorithm 18 is called for several values of $i$. It computes the JPS of the fictive activities $A_1', \ldots, A_n', A_n'+1, \ldots, A_n''$ as defined in the proof of Proposition 81.

**EndTimeJPS[1]** is the end time of $A_k'$ on JPS. If the processing time of one of these activities is
Algorithm 17 An $O(n^4)$ algorithm to compute the violations

1: for $i := 1$ to $n$ do
2: $X_i := 0.0$
3: end for
4: for $i := 1$ to $n$ do
5: if $r_i + p_i \leq d_i$ (otherwise $A_i$ is late, i.e., $X_i := 0.0$) then
6: $X_i := 1.0$, $\text{Violation} := 0.0$
7: for all constraint $(t_1, t_2)$ s.t. $t_1 \in \{r_x\}, t_2 \in \{\bar{d}_x\} \cup \{d_x\}$ do
8: total := 0.0
9: for $u := 1$ to $n$ do
10: if $t_1 \leq r_u$ and $\bar{d}_u \leq t_2$ (i.e., $A_i \in S(t_1, t_2)$) then
11: total := total + $p_u$
12: end if
13: if $t_1 \leq r_u$ and $d_u \leq t_2 < \bar{d}_u$ (i.e., $A_i \in P(t_1, t_2)$) then
14: total := total + $p_uX_u$
15: end if
16: end for
17: $\text{Violation} := \max(\text{Violation}, \text{total} - (t_2 - t_1))$
18: end for
19: $X_i := (p_i - \text{Violation})/p_i$
20: end if
21: end for

null then its end time is arbitrarily defined as its release date. JPS can be built in $O(n \log n)$ [54]. Algorithm 18 then runs in $O(n^2 \log n)$.

**Proof of the correctness of Algorithm 18.** By induction. Suppose that at the beginning of iteration $i$ (line 4), the first coordinates $X_1, \ldots, X_{i-1}$ are exactly equal to those of $Y$, the maximal vector (according to the lexicographical order) satisfying the constraints of (11.3). Consider the case $Y_i = 1$. Then, because of the structure of (11.3), there exists a feasible preemptive schedule of the fictive activities where the processing time of $A_i'$ is $p_i$. Thus, the JPS computed line 7 is also feasible; which means that no violation occurs. Hence, $X_i = 1$ (line 12). Now assume that $Y_i < 1$.

- We first prove that $X_i \leq Y_i$. Since $Y_i < 1$, the violation computed by Algorithm 17 at step $i$ is positive. Let then $(t_1, t_2)$ be the constraint that realizes this violation. We then have

$$Y_i = \frac{1}{p_i} \left( t_2 - t_1 - \sum_{A_u \in S(t_1, t_2)} p_u - \sum_{A_u \in P(t_1, t_2) \land u < i} p_uX_u \right)$$

Consider the subset of the fictive activities $A_1', \ldots, A_{n-1}', A_{n+1}', \ldots, A_{2n}'$ that have a release date greater than or equal to $t_1$ and a deadline lower than or equal to $t_2$. They cannot be completed before $t_1$ plus the sum of the processing times of these activities, i.e., before

$$t_1 + \sum_{A_u \leq t_1} p_u$$

$$= t_1 + \sum_{A_u \in S(t_1, t_2)} p_u + \sum_{A_u \in P(t_1, t_2) \land u < i} p_uX_u + p_i$$

$$= t_1 + \sum_{A_u \in S(t_1, t_2)} p_u + \sum_{A_u \in P(t_1, t_2) \land u < i} p_uX_u + p_i$$
An efficient algorithm to compute the optimum of (11.3) for well-structured instances. Figure 11.2 illustrates the use of this algorithm for a well-structured instance with 4 activities.

We have presented an efficient algorithm to compute the optimum of (11.3) for well-structured instances. Figure 11.2 illustrates the use of this algorithm for a well-structured instance with 4 activities.

If an instance is not well-structured, it is easy to relax the deadlines so that it becomes well-structured. To do so, an iteration is performed over all pairs of activities \( A_i, A_j \). If \( i < j \), \( d_i < d_j \), \( d_j < d_i \), and \( d_i > d_j \) then \( d_j \) is momentary set to \( d_i \). After this modification, the instance is well-structured and we can use Algorithm 18 to obtain a lower bound.

Notice that the algorithm does not work for non-well-structured instances. Consider the counter-example of Table 11.2. The optimum of (11.3) is 3 (\( A_1, A_2 \) and \( A_3 \) are respectively scheduled over \([2,3], [0,1]\) and \([1,2]\)). Unfortunately, the algorithms both find that \( X_1 = 1, X_2 = 0, \) and \( X_3 = 0, i.e., A_1, A_2 \) and \( A_3 \) are respectively scheduled over \([0,1], [1,2], \) and \([2,3]\).
Initial instance. In the following, we focus on the fictive activities.

Step 1: Is there a schedule where $A_1$, $A_2$, $A_3$, $A_4$ end before their latest end time? Yes.

 violates $= 0$

Step 2: Try to put $A_1$ on time (i.e., the processing time of the fictive activities $A'_1$ and $A'_2$ are set to $2$ and $0$) and compute $J_{PS}$. The maximal violation is $0$ hence, $X_1 = 1.0$.

 violates $= 2$

Step 3: Try to put $A_2$ on time (i.e., the processing time of the fictive activities $A'_3$ and $A'_4$ are set to $7$ and $0$) and compute $J_{PS}$. The maximal violation is $2$ hence, at most $5$ units of $A_2$ can be on time, i.e., $X_2 = 5/7$.

 violates $= 2$

Step 4: Try to put $A_3$ on time (i.e., the processing time of the fictive activities $A'_5$ and $A'_6$ are set to $5$ and $0$) and compute $J_{PS}$. The maximal violation is $2$ hence, at most $3$ units of $A_3$ can be on time, i.e., $X_3 = 5/3$.

 violates $= 3$

Step 5: Try to put $A_4$ on time (i.e., the processing time of the fictive activities $A'_7$ and $A'_8$ are set to $3$ and $0$) and compute $J_{PS}$. The maximal violation is $3$ hence, $A_4$ is late, i.e., $X_4 = 0$. 

Figure 11.2: Illustration of Algorithm 18
11.1.3 Constraint Propagation

In this section, some deduction rules are presented. They determine that some activities can, must or cannot end before their due date. Consider an activity $A_u$ such that $\text{eet}_u \leq d_u < \tilde{d}_u$; it can be either late or on-time. Our objective is to compute efficiently a lower bound of the weighted number of late activities if $A_u$ is on-time (conversely if $A_u$ is late). If this lower bound is greater than the maximal value in the domain of criterion then $A_u$ must be late (conversely on-time). Algorithm 18 could be used to compute such a lower bound. However, it would be called $n$ times, leading to a high overall complexity of $O(n^3 \log n)$. We propose to use a slightly weaker lower bound that can be computed, after some preprocessing, in linear time, for each activity. We will see that the overall domain reduction scheme runs in $O(n^2)$.

First, deadlines are relaxed to a very large value (except for the activities that have to be on-time), i.e., late activities can be scheduled arbitrarily late. Once this is done, we compute the optimum $X$ of the linear program obtained with the relaxed deadlines (the instance is well-structured and so we can use Algorithm 18). It is easy to see that this program can be rewritten as follows:

$$\min \sum_{i=1}^{n} w_i (1 - x_i)$$

subject to:

- $\forall r_j, \forall d_k > r_j, \sum_{A_i \in P(r_j, d_k)} p_i x_i \leq d_k - r_j$ \hspace{1cm} (11.4)
- $\forall i, r_i + p_i > d_i \Rightarrow x_i = 0$
- $\forall i, d_i \leq d_i \Rightarrow x_i = 1$
- $\forall i \in \{1, \ldots, n\}, x_i \in [0, 1]$

The second and the third constraint simply take into account the fact that some activities are known to be late (or on-time). Of course, the lower bound provided by (11.4) is weaker than the one provided by (11.3) (because deadlines have been relaxed). However, the computation of $X$ is the basis of our domain reduction scheme.

Late Activity Detection

Let (11.5) be the linear program (11.4) to which the constraint $x_u = 1$ has been added.

$$\min \sum_{i=1}^{n} w_i (1 - x_i)$$

subject to:

- $\forall r_j, \forall d_k > r_j, \sum_{A_i \in P(r_j, d_k)} p_i x_i \leq d_k - r_j$ \hspace{1cm} (11.5)
- $\forall i, r_i + p_i > d_i \Rightarrow x_i = 0$
- $\forall i, d_i \leq d_i \Rightarrow x_i = 1$
- $\forall i \in \{1, \ldots, n\}, x_i \in [0, 1]$
- $x_u = 1$

Assume that there is a feasible solution of (11.5) and let $X_o$ be the optimal vector of (11.5) obtained by Algorithm 17. Propositions 82 and 83 exhibit two relations that $X$ and $X_o$ satisfy. These relations are used to compute a lower bound of the weighted number of late activities.

**Proposition 82.** $\sum p_i X_o_i \leq \sum p_i X_i$

Proof. Let $G(I, T, E)$ be a bipartite graph, where $I = \{1, \ldots, n\}$ is a set of vertices corresponding to the activities, where $T = \{t : \min_i r_i \leq t < \max_i d_i\}$ is a set of vertices corresponding to all the “relevant” time-intervals $[t, t+1)$ and where an edge $(i, t)$ belongs to $E$ if and only if $A_i$ can execute on time in $[t, t+1)$ (i.e., $r_i \leq t < d_i$). Consider the network flow (cf. Figure 11.3) built from $G$ by adding:

- two vertices $S, P$ and an edge $(P, S)$,
- for each node $i$ an edge $(S, i)$ whose capacity is (i) upper bounded by $p_i$ and (ii) lower bounded by $p_i$ if $d_i \leq d_i$ and by 0 otherwise,
- for each node $t$ an edge $(t, P)$ whose capacity is upper bounded by 1.

A flow $f$ on $G$ corresponds to a preemptive schedule of the activities where $f(S, i)$ units of each activity are on-time and where the remaining units are late; $f(x, y)$ being the value of the flow through the edge $(x, y)$. Hence, to any feasible flow $f$ we can associate the vector $X$ that meets all the constraints of (11.4):

$$X_i = \frac{f(S, i)}{p_i}$$

Conversely, a feasible flow can be derived from any vector $X$ meeting all the constraints of (11.4) such that $p_i X_i$ is integer: Compute the JPS of the activities with a processing time of $p_i X_i$ and set $f(i, t) = 1$ if and only if one unit of $J_i$ executes at time $t$ on JPS.

Suppose that $\sum p_i X_o > \sum p_i X_i$ then the flow corresponding to $X$ is not maximal in $G$ and thus there is an augmenting path from $S$ to $P$. Let then $X^+$ be the vector corresponding to the augmented flow. Because of the structure of $G$, $\forall i, X_i^+ \geq X_i$. On top of that there exists $t$ such that $X^+_i > X_i$. This contradicts proposition 81.

![Figure 11.3: Network flow associated to the graph $G$](image)

**Proposition 83.** $\forall i \neq u, X_o \leq X_i$

Proof. Suppose the proposition does not hold. Let $i$ be the first index such that $i \neq u$ and $X_o > X_i$. We modify the instance of the problem by removing the activities $A_v$ with $v > i$ that do not have to be on-time (i.e., $v \neq u$ and $d_v > d_u$). The activities that have been removed do not influence Algorithm 17 when computing the $i$ first coordinates of $X$ and of $X_o$ (i.e., for the modified instance, the $i$ first coordinates of the optimum vector are exactly those of $X$). Now, consider the modified instance. We still have $i \neq u$ and $X_o > X_i$. Moreover, the activities that have a greater index than $i$ are on-time. Consider the modified network (Figure 11.4) built from the bipartite graph $G$ by adding:

- two vertices $S, P$ and an edge $(P, S)$,
- for each node $i$ an edge $(S, i)$ whose capacity is (i) upper bounded by $p_i$ and (ii) lower bounded by $p_i$ if $d_i \leq d_i$ and by 0 otherwise,
- for each node $t$ an edge $(t, P)$ whose capacity is upper bounded by 1.
three vertices $S', S$, and two edges, $(S, S')$ and $(P, S)$,
for each node $v$ ($v \neq i$) an edge $(S', v)$ whose capacity is (i) upper bounded by 0 if $A_v$ has to be late and by $p_v$ otherwise and (ii) lower bounded by $p_v$ if $A_v$ has to be on-time and by 0 otherwise,
an edge $(S, i)$ whose capacity is upper bounded by $p_i$ and lower bounded by 0,
for each node $t$ an edge $(t, P)$ whose capacity is upper bounded by 1.

For any feasible flow, a vector satisfying all constraints of (11.4) can be built. Conversely, for any vector satisfying all constraints of (11.4), a feasible flow can be built. The flow corresponding to $X_0$ is obviously feasible. Moreover the flow on $(P, S)$ for vector $X$ is greater than or equal to the one for $X_0$ (see Proposition 82). Moreover, the flow on $(S, i)$ for $X$ is greater than the one for $X_0$. Hence, because of the conservation law at $S$, the flow that goes over $(S, S')$ is not maximal for $X_0$. As a consequence, there is an augmenting path from $S'$ to $S$ for the flow corresponding to $X$. Let then $X^+$ be the vector corresponding to the augmented flow. Because of the structure of $G$, $\forall v \neq i, X^+_v \geq X_0_v$. Hence, for any activity that has to be on-time, $X^+_v = 1$ and then $X^+$ satisfies all the constraints of (11.5). Moreover it is better than $X_0$ because:

- If the edge $(P, S)$ is in the augmenting path then $\sum p_i X^+_i > \sum p_i X_0_i$.
- If the edge $(i, S)$ is in the augmenting path then we claim that $X^+_i$ is greater, for the lexicographical order, than $X_0$. Indeed, there is an edge from $S'$ to an activity, say $v$, in the augmenting path. Hence, $A_v$ does not have to be on-time (otherwise, the edge would be saturated for $X_0$ and it could not belong to the augmenting path). Consequently, $v < i$ and then $X^+_i > X_0_v$.

This contradicts the fact that $X_0$ is optimal.

Thanks to Propositions 82 and 83, we can add constraints $\sum p_i X_0_i \leq \sum p_i X_i$ and $\forall i \neq u, x_i \leq X_i$ to the linear program (11.5). Since we are interested in a lower bound of (11.5), we can also relax the resource constraints. As a consequence, we seek to solve the following program (11.6) that is solved in linear time by Algorithm 19.

$$\min \sum_{i=1}^n w_i (1 - x_i)$$

u.c. $\begin{align*}
\sum p_i x_i &\leq \sum p_i X_i \\
\forall i \neq u, x_i &\leq X_i \\
x_u &= 1 \\
\forall i \in \{1, \ldots, n\}, x_i &\in [0, 1]
\end{align*}$

Algorithm 19 A linear time algorithm for late activity detection

1: for $i := 1$ to $n$ do
2: \hspace{1cm} $X_0_i := 0.0$
3: end for
4: $X_0_u := 1$
5: $MaxVal := \sum p_i X_i - p_u$
6: for $i := 1$ to $n$ and $i \neq u$ do
7: \hspace{1cm} $X_0_i := \min(X_i, MaxVal/p_i)$
8: \hspace{1.5cm} $MaxVal = MaxVal - p_i \times X_0_i$
9: end for
On-Time Activity Detection

Let $A_u$ be an activity such that $eet_u \leq d_u < \bar{d}_u$. $A_u$ can be either late or on-time. We want to compute a lower bound of the number of late activities if it is late. Let $X_l$ be the optimal vector of the linear program (11.4) to which the constraint $x_u = 0$ has been added. We claim that $P_p i X_l i \leq P_p i X i$ and that $8 i 6 = u; X_l i \neq X i$ (proofs are similar to the proofs of Propositions 82 and 83). The same mechanism than for the late activity detection then applies: The new constraints are entered in the linear program while the resource constraints are removed. The resulting linear program can be also solved in linear time.

Example

Consider the instance of Figure 11.2. Deadlines are relaxed. The optimal vector of (11.4) is $X_1 = 1, X_2 = 5/7, X_3 = 3/5, X_4 = 0$. The lower bound is then $(0 * 10)/2 + (2 * 30)/7 + (2 * 20)/5 + (3 * 5)/3 = 21.57$ Assume that the domain of criterion is $[22, 26]$. Let us try to put $A_4$ on-time. The optimum of (11.6) is $X_0_1 = 1, X_0_2 = 5/7, X_0_3 = 0, X_0_4 = 1$. Thus, the new lower bound is $(0 * 10)/2 + (2 * 30)/7 + (5 * 20)/5 + (0 * 5)/3 = 28.57$. Given the domain of criterion, we deduce that $A_4$ must be late.

11.2 Total Tardiness

We propose a set of techniques\(^1\), to propagate the $\sum T_i$ criterion. We restrict our study to the single machine case and unfortunately, extensions to cumulative problems are not straightforward. We also assume that there are no initial deadlines (i.e., those that appear in the following algorithms have been deduced by some dominance rules).

The single machine total tardiness scheduling problem has been widely studied in the literature (see Section 14.2 for a brief review). Many dominance properties have been proposed in the case where $\forall i, r_i = 0$. In comparison, less efficient lower-bounds have been introduced. In this section, we focus on constraint propagation, a purely deductive process in which dominance rules cannot a priori be incorporated. However, we will see that some new dominance rules can be used as a preprocessing step to compute a very efficient lower bound.

11.2.1 Lower Bounds

Relaxing non-preemption is a standard technique to obtain lower bounds for non-preemptive scheduling problems. Unfortunately, the total tardiness problem with no release dates (for which the preemption is not useful) is already NP-Hard, so some additional constraints have to be relaxed to

\(^1\) All the results presented in this section come from [16]
obtain a lower bound in polynomial time. From now on, assume that activities are sorted in non-decreasing order of due dates. We first recall Chu’s lower bound. Latter we will show how some new dominance properties can be used to improve this lower bound.

Chu [75] has introduced an $O(n \log n)$ lower bound, $lb_{Chu}$, that can be computed as follows. Preemption is relaxed and activities are scheduled according to the SRPT (Shortest Remaining Processing Time) rule. Each time an activity becomes available or is completed, an activity with the shortest remaining processing time among the available and uncompleted activities is scheduled (see Table 11.3 and Figure 11.5). The computation of the lower bound is based on Proposition 84 ([75]).

**Proposition 84.** Let $[i]$ denote the index of the activity which is completed in the $i^{th}$ position in the SRPT schedule. The total tardiness is at least

$$\sum_{i=1}^{n} \max(C_{[i]} - d_i, 0).$$

**11.2.2 Improving Lower Bounds With Dominance Properties**

A dominance rule is a constraint that can be added to the initial problem without changing the value of the optimum, i.e., there is at least one optimal solution of the problem for which the dominance holds. Dominance rules can be of prime interest since they can be used to reduce the search space. However they have to be used with care since the optimum can be missed if conflicting dominance rules are combined.

**Emmons Rules**

We recall Emmons Rules and generalize them to take into account release dates. Unfortunately, these rules are valid if preemption is allowed (or, for some of them, if activities have identical processing times). Nevertheless, we will see in Section 11.2.2 that these rules can be used in a pre-processing phase before computing a preemptive lower-bound of the problem.

**Initial Emmons Rules**

Emmons [95] has proposed a set of dominance rules for the special case where release dates are equal ($1||\sum T_i$). These rules allow us to deduce some precedence relations between activities. Following Emmons notation, $A_i$ and $B_i$ are the sets of activities that have to be scheduled, according to the dominance rules, respectively after and before $A_i$. In the following, we say that $A_i$ precedes $A_k$ when there is an optimal schedule in which $A_i$ precedes $A_k$ and for which all previously mentioned dominance properties hold.
Emmons Rule 1. \( \forall i, k(i \neq k), \) if \( p_i \leq p_k \) and \( d_i \leq \max(\sum_{A_j \in B_k} p_j + p_k, d_k) \) then \( A_i \) precedes \( A_k \) \((A_i \in B_k \) and \( A_k \in A_i))\).

Emmons Rule 2. \( \forall i, k(i \neq k), \) if \( p_i \leq p_k \) and \( d_i > \max(\sum_{A_j \in B_k} p_j + p_k, d_k) \) and \( d_i + p_i \geq \sum_{A_j \notin A_k} p_j \), then \( A_k \) precedes \( A_i \).

Emmons Rule 3. \( \forall i, k(i \neq k), \) if \( p_i \leq p_k \) and \( d_k \geq \sum_{A_j \notin A_i} p_j \), then \( A_i \) precedes \( A_k \).

Generalized Emmons Rules

Our aim is to generalize Emmons rules to the situation where we have arbitrary release dates. Such a generalization is relatively easy to do if we relax the non-preemption constraint. We will see that the resulting rules can be used to tighten the lower bound of the non preemptive problem (Section 11.2.2).

In the preemptive case, \( A_i \) is said to precede \( A_k \) if and only if \( A_k \) starts after the end of \( A_i \). As for the initial Emmons rules, \( A_i \) and \( B_i \) respectively denote the set of activities that are known to execute after and before \( A_i \).

Note that active schedules are dominant, i.e., we only consider schedules in which activities or pieces of activities cannot be scheduled earlier without delaying another activity. It is easy to see that all active schedules have exactly the same completion time \( C_{\text{max}} \). To compute this value, we can build the schedule where activities are scheduled in non decreasing order of release dates. Now we can tighten the deadlines since \( A_i \) since it cannot be completed after \( C_{\text{max}} - \sum_{A_j \in A_i} p_j \). These deadlines are only valid in the preemptive case.

In the following, we note \( C_{\text{max}}(E) \) the completion time of active schedules of a subset \( E \) of activities (other activities are not considered). As mentioned previously, all active schedules have the same completion time and it can be computed in polynomial time. \( C_{\text{max}}(E) \) is a lower bound of the maximal completion time of the activities of \( E \) in any schedule of \( \{A_1, \ldots, A_n\} \). If \( B_i \) is a set of activities that have to be processed before \( A_i \), then \( A_i \) cannot start before \( C_{\text{max}}(B_i) \), i.e., the release date \( r_i \) can be adjusted to \( \max(r_i, C_{\text{max}}(B_i)) \).

First, we make the following remark which allows us to compare the values of the tardiness of an activity \( A_i \) in two schedules \( S \) and \( S' \): Let \( C_i \) and \( C'_i \) be the completion times of \( A_i \) on two preemptive schedules \( S \) and \( S' \) and let \( T_i \) and \( T'_i \) be respectively the tardiness of \( A_i \) in \( S \) and \( S' \).

- If \( C'_i < C_i \) and \( d_i \leq C_i \) then \( T'_i - T_i = \max(C'_i, d_i) - C_i \leq 0 \).
- If \( d_i \geq \max(C_i, C'_i) \) then \( A_i \) is on time in \( S \) and in \( S' \) and \( T'_i - T_i = 0 \).

Generalized Emmons Rule 1. Let \( A_i \) and \( A_k \) be two activities such that \( r_i \leq r_k \), \( p_i \leq p_k \) and \( d_i \leq \max(r_k + p_k, d_k) \), then \( A_i \) precedes \( A_k \) \((A_i \in B_k \) and \( A_k \in A_i))\).

Proof. Consider a schedule \( S \) in which activity \( A_i \) and activity \( A_k \) satisfy the assumptions. First,

\[
\begin{array}{cccccc}
A_k & A_k & A_i & A_k & A_i \\
A_i & A_i & A_k & A_k & A_k \\
C_i & d_i & C_k & d_k & C_i \\
\end{array}
\]

Figure 11.6: Generalized Emmons Rule 1.

assume that activity \( A_k \) is completed before activity \( A_i \) \((C_k < C_i)\). Let us reschedule the pieces of \( A_i \) and \( A_k \) such that all pieces of \( A_i \) are completed before the pieces of \( A_k \) (see Figure 11.6). Note that the exchange is valid since \( r_i \) is lower than or equal to \( r_k \). We show that this exchange does
not increase total tardiness. Let $S'$ be this new schedule and let $C'_i$ be the completion time of $A_i$ in $S'$. In $S'$, $A_k$ is completed at time $C_i$. If $C_i \leq d_i$, the activities $A_i$ and $A_k$ are on time in the two schedules $S$ and $S'$ and the exchange has no effect. From now, we suppose that $d_i < C_i$.

Since the completion times of all other activities remain the same, the difference between the total tardiness of $S'$ and of $S$ is exactly $\Delta = T'_i - T_i + T_k' - T_k$. Following our initial remark, $T'_i - T_i = \max(C'_i, d_i) - C_i$ and $T_k' - T_k = C'_k - \max(C_k, d_k) = C_i - \max(C_k, d_k)$. So, $\Delta = \max(C'_i, d_i) - \max(C_k, d_k)$. Note that all pieces of $A_i$ are completed before $C_k$ in $S'$ and since $p_i \leq p_k$, we have $C'_i \leq C_k$ and $\Delta \leq \max(C_k, d_k) - \max(C_k, d_k)$.

Now consider two cases:

- If $\max(r_k + p_k, d_k) = d_k$ then $d_i \leq d_k$. Together with $C'_i \leq C_k$, this leads to $\Delta \leq 0$.
- If $\max(r_k + p_k, d_k) = r_k + p_k$ then $d_i \leq r_k + p_k \leq C_k$ and $d_k \leq r_k + p_k \leq C_k$. This leads to $\Delta \leq C_k - C_k = 0$.

Now assume, that activity $A_i$ is completed before activity $A_k$. Rescheduling the pieces of the two activities, such that all pieces of $A_i$ are completed before the pieces of $A_k$, can only decrease the tardiness of $A_i$, and leave unchanged the tardiness of $A_k$.

In all cases, the exchange does not increase total tardiness.

As shown in Figure 11.7, the Generalized Emmons Rule 1, does not hold in the non-preemptive case. Indeed, $A_1$ would have to be completed before $A_2$, which is not true in the non-preemptive case.

![Figure 11.7: An Optimal Non-Preemptive Schedule and an Optimal Preemptive Schedule.](image)

The proof for the two following rules follow the same scheme as above (see [16]).

**Generalized Emmons Rule 2.** Let $A_i$ and $A_k$ be two activities such that $r_i \leq r_k$, $d_i \leq d_k$ and $\bar{d}_i \leq d_k + p_k$, then $A_i$ precedes $A_k$.

**Generalized Emmons Rule 3.** Let $A_i$ and $A_k$ be two activities such that $r_i \leq r_k$ and $\bar{d}_i \leq d_k$, then $A_i$ precedes $A_k$.

**Combining Generalized Emmons Rules**

As mentioned previously, dominance properties cannot always be combined. Fortunately, in our case, the Generalized Emmons Rules are compatible, which was already the case for $1||\sum T_i$ as noticed by Emmons [95].

We can use these dominance rules one after the other to adjust the data of an instance: if a set $B_i$ of activities is proved to precede $A_i$ according to the Generalized Emmons Rules, it is possible to adjust $r_i$ to $r_i = \max(r_i, C_{\max}(B_i))$. By using iteratively these rules, we are sure, that at the end of each iteration, the adjusted instance has the same optimal total tardiness than the original instance, and that we have not introduce any inconsistencies.

We consider activities one after the other and each time we perform adjustments. Now, we can prove that we do not introduce any inconsistencies. Indeed, suppose that at the current iteration, we have for each activity $A_i$, a set $B_i$ of activities which are proven to precede $A_i$, and a set $A_i$ of activities which are proven to follow $A_i$. Suppose too that there is no contradiction at this time and that all adjustments are made considering these sets. It means that we have $r_j < r_i$, for any $A_j \in B_i$ and $r_i < r_j$, for any $A_j \in A_i$. Suppose now, we want to refine the adjustments for an
activity $A_k$. Let $A_i \notin B_k$ be an activity which has not yet been proved to precede $A_k$, but for which, one of the Generalized Emmons Rule has proven that $A_i$ precedes $A_k$. This implies that $r_i \leq r_k$. According to this rule, we can introduce a contradiction only if there exists an activity $A_m$ such that: $A_k$ precedes $A_m$ and $A_m$ precedes $A_i$. Because we have made all adjustments implied by the precedence relations already established, we have: $A_k$ precedes $A_m$ implies $r_k < r_m$, and $A_m$ precedes $A_i$ implies $r_m < r_i$, then $r_k < r_m < r_i$, which contradicts the initial assumption $r_i \leq r_k$. Consequently, we will not introduce any inconsistency according to the precedence relations already established.

Each rule can be implemented in $O(n^2)$. The activities are sorted in non-decreasing order of release dates in a heap structure, which runs in $O(n \log n)$. For each activity $A_i$, we consider the set of activities which are completed before $A_i$ according to the Generalized Emmons Rules. Computing the earliest completion time of this set and adjusting $r_i$ runs in $O(n)$, since the activities are already sorted in non-decreasing order of release dates. The heap structure is maintained in $O(\log n)$. Therefore, we have an overall time complexity of $O(n)$ for each activity. New precedence dominances can be found and the rules might have to be applied again. Each activity can be adjusted at most $n - 1$ times. Hence, in the worst case the whole propagation is in $O(n^3)$.

### A New Lower Bound

We introduce two propositions, that are valid in the preemptive case only. Proposition 85 is a weak version of the Generalized Emmons Rule 1. Proposition 86 shows that under some conditions, due dates can be exchanged without increasing the objective function.

**Proposition 85.** Let $A_i$ and $A_k$ be two activities such that $r_i \leq r_k$, $p_i \leq p_k$ and $d_i \leq d_k$, then there exists an optimal schedule in which $A_k$ starts after the end of $A_i$.

**Proof.** See proof of Generalized Emmons Rule 1. □

**Proposition 86.** Let $A_i$ and $A_k$ be two activities such that $r_i \leq r_k$, $p_i \leq p_k$ and $d_i > d_k$. Exchanging $d_i$ and $d_k$ does not increase the optimal total tardiness.

**Proof.** Consider an optimal schedule $S$ of the original instance and let $C_i$ and $C_k$ be the completion times of $A_i$ and $A_k$ in $S$. Let $\Delta$ be the difference between the tardiness of $S$ before and after the exchange.

$$\Delta = \max(0, C_i - d_k) + \max(0, C_k - d_i) - \max(0, C_i - d_i) - \max(0, C_k - d_k).$$

First, assume that $C_i < C_k$ and consider the following cases.

If $d_k < d_i \leq C_i$ then

$$\Delta = (C_i - d_k) + (C_k - d_i) - (C_i - d_i) - (C_k - d_k) = 0.$$

If $d_k \leq C_i \leq d_i \leq C_k$ then

$$\Delta = (C_i - d_k) + (C_k - d_i) - (C_k - d_k) = C_i - d_i \leq 0.$$

If $C_i \leq d_k < d_i \leq C_k$ then $\Delta = 0 + (C_k - d_i) - (C_k - d_k) = d_i - d_k \leq 0$.

If $C_i \leq d_k \leq C_k \leq d_i$ then $\Delta = 0 + 0 - (C_k - d_k) \leq 0$.

If $C_i < C_k \leq d_k < d_i$ then $\Delta = 0$.

If $d_k \leq C_i < C_k \leq d_i$ then

$$\Delta = (C_i - d_k) + 0 - (C_k - d_k) = (C_i - C_k) + (d_k - d_i) < 0.$$

Now assume that $C_k < C_i$. After the exchange of due dates, we exchange the pieces of the activities, such that all pieces of $A_i$ are scheduled before those of $A_k$. This exchange is valid since $r_i \leq r_k$. In this new schedule, $A_i$ is completed before or at $C_k$ because $p_i \leq p_k$, thus the tardiness of $A_i$ is lower than or equal to $\max(0, C_k - d_k)$. Moreover, $A_k$ is completed at $C_i$ and its tardiness is equal to $\max(0, C_i - d_i)$. Thus $\Delta \leq \max(0, C_i - d_i) + \max(0, C_k - d_k) - \max(0, C_i - d_i) - \max(0, C_k - d_k) \leq 0$. □
These propositions allow us to compute a lower bound $lb_1$ thanks to the following algorithm.

At each time $t$, we consider $D = \{A_j | r_j \leq t \land p'_j > 0\}$ the set of activities available but not completed at $t$ ($p'_j$ denotes the remaining processing time of $A_j$ at time $t$). Let $A_u$ be the activity with the shortest remaining processing time, and let $A_v$ be the activity with the smallest due date. If $d_u = d_v$, i.e., $A_u$ has the smallest due date, according to Proposition 85, it is optimal to schedule one unit of this activity. If it is not the case, according to Proposition 86, we exchange its due date with the one of $A_u$, the activity with the smallest due date. This new instance has an optimal total tardiness lower than or equal to the optimal tardiness of the original problem. In this new problem, $A_u$ has now the smallest due date and the smallest remaining processing time, then it is optimal to schedule one unit of this activity according to Proposition 85. We increase $t$ and we iterate until all activities are completed.

At each time $t$, we build a new problem by exchanging two due dates. This new problem has an optimal total tardiness lower than or equal to the problem before. Hence, at the end of the algorithm, we obtain an optimal schedule of a problem which has a total tardiness lower than or equal to the optimal tardiness of the original problem. Therefore, it is a lower bound of the original problem. Actually, the only relevant time points are when an activity becomes available or when an activity is completed. And so there are at most $2n$ times $t$ to consider.

We maintain two heaps $heap_p$ and $heap_d$ which contain respectively, the uncompleted activities which are available at time $t$ sorted in non-decreasing order of remaining processing times, and these activities sorted in non-decreasing order of due dates. The insertion, the extraction and the modification of an activity of one heap costs $O(\log n)$. Getting the minimum element of one heap costs $O(1)$. We have at most $n$ insertions (each time an activity becomes available), and at most $n$ extractions (each time an activity is completed). At each time $t$, we have at most two modifications in $heap_p$ and in $heap_d$ when we must exchange the due dates of two activities. Hence, our algorithm runs in $O(n \log n)$.

**Comparison with Chu’s Lower Bound**

The schedule built by our algorithm is the same as the one built by Chu. The algorithms differ from the assignment of the due dates to the activities. Indeed, in the algorithm of Chu, the assignment of the due dates is performed at a “global” level, whereas in our algorithm, the assignment is performed at a “local” level. We show that $lb_1$ is strictly better than $lb_{Chu}$.

**Proposition 87.** The lower bound $lb_1$ obtained by our algorithm is stronger than Chu’s lower bound $lb_{Chu}$.

*Proof.* The sets of completion times in the schedules built by our algorithm and by Chu’s are the same. The difference lies in the assignment of due dates to the activities. Let $(d_1, \ldots, d_n)$ be the sequence of due dates sorted in non-decreasing order. This is the sequence obtained by the algorithm of Chu. Let $(d_{\sigma(1)}, \ldots, d_{\sigma(n)})$ be the sequence of due dates obtained by our algorithm. Let $j$ be the first index such that $j \neq \sigma(j)$ and let $t$ be the starting time of the piece of activity which is completed at $C_{\sigma(j)}$. This piece is a piece of the activity with the shortest remaining processing time at $t$. We have $d_j \in (d_{\sigma(j+1)}, \ldots, d_{\sigma(n)})$ and $d_j \leq d'_j$. Let $T'$ be the tardiness associated with the sequence $(d_{\sigma(j+1)}, \ldots, d_{\sigma(n)})$. Let $k$ be the integer such that $\sigma(k) = j$. Suppose we exchange the due dates $d_{\sigma(j)}$ and $d_{\sigma(k)}$ in the sequence $(d_{\sigma(j)}, \ldots, d_{\sigma(n)})$. As a result, the decrease of the total tardiness is equal to $\max(0, C_i - d_{\sigma(j)}) + \max(0, C_k - d_{\sigma(k)}) - \max(0, C_i - d_{\sigma(k)}) - \max(0, C_k - d_{\sigma(j)})$ which is non-negative as shown in the first part of the Proposition 86 because $C_i < C_k$ and $d_{\sigma(k)} \leq d_{\sigma(j)}$. Now the two sequences are identical up to index $j + 1$. We iterate until the sequences are the same. Hence $lb_{Chu} \leq lb_1$. \qed

We provide an example for an instance with 3 activities, for which $lb_1$ is equal to 1 whereas $lb_{Chu}$ is equal to 0 (see Table 11.4 and Figure 11.8). For this instance, $lb_1$ is the optimal total tardiness.
Improving the Lower Bound

To improve our lower bound, we extensively use the Generalized Emmons Rules as a pre-processing step before the computation of the lower bound. The lower bound is valid in the preemptive case hence, we can apply the Generalized Emmons Rules. They allow us to tighten the release dates, which has a dramatic impact on the value of the lower bound.

Recall that, to compute our lower bound, we chronologically build a preemptive schedule (see Section 11.2.2). We still follow the same algorithm but, at each time point where a piece of activity to schedule next has to be chosen, we apply the Generalized Emmons Rules on the activities that are not scheduled yet.

Since there are $O(n)$ relevant time points and since the propagation of the Generalized Emmons Rules runs in $O(n^3)$, the improved lower bound can be computed in $O(n^4)$. In practice, the propagation of the Generalized Emmons Rules is much “faster” than $O(n^3)$ and the bound is computed in a reasonable amount of time. In the following we use the notation $lb_2$ to refer to this bound.

11.2.3 Constraint Propagation

Focacci [102] has recently proposed an original approach based on Constraint Programming to compute a lower bound of $\sum_{i=1}^{n} T_i$. In this approach, each activity is associated with a constrained variable identifying all possible positions (first, second, third, etc.) that the activity can assume in a schedule. Following this idea, we present some rules that deduce that an activity cannot be executed in some positions. This information allows us to adjust the release dates.

From now on, we assume that activities are sorted in non-decreasing order of due dates.

As in Section 11.2.1, $[i]$ denotes the index of the activity which is completed in the $i^{th}$ position in the SRPT schedule. We know that $C_{[i]}$ is a lower bound of the completion time of the activity scheduled in $i^{th}$ position and according to Proposition 84, $\sum_{i=1}^{n} \max(C_{[i]} - d_i, 0)$ is a lower bound of the total tardiness (each activity $A_i$ is assigned to the completion time $C_{[i]}$).

Suppose now that we want to compute a lower bound of the total tardiness under the hypothesis that $A_i$ is scheduled in the $k^{th}$ position. We first assign the completion time $C_{[k]}$ to $A_i$ and we reassign all other completion times to all other activities as follows.

- If $k < i$ the activities $A_k, A_{k+1}, \ldots, A_{i-1}$ are assigned to $C_{[k+1]}, C_{[k+2]}, \ldots, C_{[i]}$ and the other assignments do not change.
Following these new assignments, we have a new lower bound. If it is greater than criterion (the value of the objective function), then \( A_i \) cannot be in the \( k^{th} \) position.

Now assume that we have shown that positions 1, \ldots, \( k \) are not possible for an activity \( A_i \) then \( A_i \) cannot be completed before \( C_{[k+1]} \) and cannot start before \( C_{[k]} \). Hence, the release date \( r_i \) can be adjusted to \( \max(r_i, C_{[k+1]} - p_i, C_{[k]}) \). Moreover, if \( k > 1 \) then \( i \) cannot be scheduled first. Of course, symmetric rules hold when it is known that the last \( k \) positions are not possible for \( A_i \).

To implement this constraint propagation rule, we just have to use the \( O(n \log n) \) algorithm of Chu [75], to compute the values \( C_{[1]}, C_{[2]} \ldots, C_{[n]} \). Then, for each activity \( A_i \) and for each position \( k \), the lower-bound can be recomputed in linear time thanks to the reassignment rules provided above. This leads to an overall time complexity of \( O(n^3) \).

Actually, this algorithm can be improved as follows. Assume that we have computed the lower bound under the assumption that \( A_i \) is scheduled in position \( k \). To compute the lower bound under the assumption that \( A_i \) is scheduled in position \( k - 1 \), we just have to exchange the assignments of activity \( i \) and activity \( [k-1] \). The modification of the lower bound is then \( \max(0, C_{[k-1]} - d_i) - \max(0, C_{[k]} - d_i) \). Hence, we can “try” all possible positions for \( A_i \) in linear time. All impossible positions can thus be computed in \( O(n^2) \).

### 11.3 Sum of Transition Times and Sum of Transition Costs

In this section we pay attention to constraint propagation of transition time and transition cost constraints. To simplify the presentation, we only consider the case where there are no cumulative constraints.

In this section we pay attention to constraint propagation of transition time and transition cost constraints. To simplify the presentation, we only consider the case where there are no cumulative constraints.

In this section we pay attention to constraint propagation of transition time and transition cost constraints. To simplify the presentation, we only consider the case where there are no cumulative constraints.

In this section we pay attention to constraint propagation of transition time and transition cost constraints. To simplify the presentation, we only consider the case where there are no cumulative constraints.
the constraint, each start node \( n + m + u \) has its \( \text{prev}_{n+m+u} \) variable bound to the corresponding end node \( \text{prev}_{n+m+u} = n + u \), and each end node \( n + u \) has its \( \text{next}_{n+u} \) variable bound to the corresponding start node \( \text{next}_{n+u} = n + m + u \). There furthermore exists a transition cost \( c^u_{ij} \) that expresses that if node \( j \) is visited directly after node \( i \) on a route \( u \) (\( \text{next}_i = j, \text{route}_i = \text{route}_j = u \)), a cost \( c^u_{ij} \) is induced. A feasible solution is defined as an assignment of distinct values to each next variable, while avoiding sub-tours (tours containing only internal nodes), and respecting the constraints

\[
\begin{align*}
\text{next}_i &= j \quad \Leftrightarrow \quad \text{prev}_j = i \\
\text{next}_i &= j \quad \Rightarrow \quad \text{route}_i = \text{route}_j
\end{align*}
\]

The problem is then to find an optimal feasible solution, \( i.e., \) a feasible solution that minimizes

\[
\sum_{i=1}^{n} c^u_{inext_i}
\]

(11.7)

As said, the routing problem described constitutes a relaxation of the global scheduling problem. If an internal node \( i \) has its next variable assigned to another internal node \( j \), activity \( A_i \) directly precedes activity \( A_j \). If an internal node \( i \) has its next variable assigned to an ending node \( n + u \), activity \( A_i \) is the last activity scheduled on machine \( M_u \). The transition costs \( c^u_{ij} \) of the routing problem correspond to the setup times (\( \text{setup}(A_i, A_j, M_u) \)) or setup costs (\( \text{setupCost}(A_i, A_j, M_u) \)) between activities; therefore the minimization of the total transition cost (11.7) in the routing problem corresponds to the minimization of the sum of setup times or setup costs in the scheduling problem.

### 11.3.1 Route Optimization Constraint

In this section, we describe the constraint propagation given in [103]. One of the basic ideas is to create a global constraint having a propagation algorithm aimed at removing those assignments from variable domains which do not improve the best solution found so far. Domain reduction is achieved by optimally solving a problem which is a relaxation of the original problem.

We consider the Assignment Problem [82] as a relaxation of the routing problem described and thus also of the global scheduling problem. The Assignment Problem is the graph theory problem of finding a set of disjoint sub-tours such that all the vertices in a graph are visited and the overall cost is minimized.

In the routing problem we look for a set of \( m \) disjoint routes each of them starting from a start node and ending in the corresponding end node covering all nodes in a graph, \( i.e., \) considering that each end node is connected to the corresponding start node, we look for a set of \( m \) disjoint tours each of them containing a start node. This problem can be formulated as an Assignment Problem on the graph defined by the set of nodes in the routing problem and the set of arcs \((i, j)\) such that \( j \in \text{domain}(\text{next}_i) \). The cost on arc \((i, j)\) is the minimal setup cost (or time), \( i.e., \)

\[
\min_{u \in \text{domain}(\text{route}_i) \cap \text{domain}(\text{route}_j)} \text{setupCost}(A_i, A_j, M_u).
\]

The value of the optimal solution of the Assignment Problem is obviously a lower bound on the value of the optimal solution of the routing problem. The primal-dual algorithm described in [65] provides an optimal integer solution for the Assignment Problem with a \( O(n^3) \) time complexity. Besides this optimal assignment with the corresponding lower bound \( LB \) on the original problem, a reduced cost matrix \( \hat{c} \) is obtained. Each \( \hat{c}_{ij} \) estimates the additional cost to be added to \( LB \) if variable \( \text{next}_i \) takes the value \( j \). These results can be used both in constraint propagation as in the definition of search heuristics. The lower bound \( LB \) is trivially linked to the \text{criterion} \ variable representing the objective function through the constraint \( LB \leq \text{criterion} \). More interesting is the propagation based on reduced costs. Given the reduced cost matrix \( \hat{c} \), it is known that \( \text{LB}_{\text{next}_i = j} = LB + \hat{c}_{ij} \) is a valid lower bound for the problem where \( \text{next}_i \) takes the value \( j \). Therefore we can impose

\[
\text{LB}_{\text{next}_i = j} > ub(\text{criterion}) \Rightarrow \text{next}_i \neq j
\]
As said, solving the Assignment Problem at the root can be done in \(O(n^3)\). Each following assignment recomputation due to domain reduction can be done in \(O(n^2)\) time though (see [65] for details). The reduced cost matrix is obtained without extra computational effort. Thus, the total time complexity of the constraint propagation algorithm is \(O(n^2)\).

The following improvement of the use of the reduced costs is also exploited. We want to evaluate if value \(j\) could be removed from the domain of variable \(\text{next}_i\) on the basis of its estimated cost. Let \(\text{next}_i = k\) and \(\text{next}_i = j\) in the optimal assignment. In order to assign \(\text{next}_i = j\), \(l\) and \(k\) must be re-assigned. The exact cost of this re-assignment can be calculated in \(O(n^2)\), thus increasing the global complexity of the constraint propagation algorithm. In [104], two bounds on this cost have been proposed, the calculation of which does not increase the total time complexity of the constraint propagation algorithm, which therefore remains \(O(n^2)\). The events triggering this propagation are changes in the upper bound of the objective function variable \(\text{criterion}\) and each change in the domains of the \(\text{next}\), \(\text{prev}\), and \(\text{route}\) variables. Note that the assignment is recomputed only when the cost of an arc \((i, j)\) that is part of the current solution increases its value over a certain threshold. The threshold \(T\) can be calculated as the minimum between the minimal reduced cost on row \(i\) and the minimal reduced cost on column \(j\) (excluding the zero reduced cost \(\bar{c}_{ij}\)).

\[
T = \min_{k \neq j}(\min_{k \neq i}(\bar{c}_{ik})), \min(\bar{c}_{kj})
\]

Recomputing the assignment is needed every time the removed value \(j\) from \(\text{next}_i\) belongs to the solution of the Assignment Problem (cost \(c_{ij}\) is set to infinite), and it may be needed when the reduction of the domain of \(\text{route}_i\) or \(\text{route}_j\) increases the minimal cost that is to be paid to go from \(i\) to \(j\) in any of the remaining possible routes. In all other cases no recomputation is needed since an increase in the cost of an arc that does not belong to the optimal solution does not change the optimal solution itself.

We remark that reduced cost fixing appears to be particularly suited for CP. In fact, while reduced cost fixing is extensively used in OR, it is usually not exploited to trigger other constraints, but only in the following lower bound computation, \(i.e.,\) the following node in the search tree. When embedded in a CP framework, the reduced cost fixing produces domain reductions which usually trigger propagation from other constraints in the problem through shared variables.

### 11.3.2 Precedence Graph Constraint

Linking the routing model and the scheduling model is done thanks to a precedence graph constraint. This constraint maintains for each machine \(M_u\) an extended precedence graph \(G_u\) that allows to represent and propagate temporal relations between pairs of activities on the machine as well as to dynamically compute the transitive closure of those relations. More precisely, \(G_u\) is a graph whose vertices are the alternative activities \(A_i^u\) that may execute on machine \(M_u\) (see Section 7.2.4). A node \(A_i^u\) is said to **surely contribute** if machine \(M_u\) is the only possible machine on which \(A_i\) can be processed. Otherwise, if activity \(A_i\) can also be processed on other machines, the node \(A_i^u\) is said to **possibly contribute**. Two kinds of edges are represented on \(G_u\):

- A **precedence edge** between two alternative activities \(A_i^u \rightarrow A_j^u\) means that if machine \(M_u\) is chosen for both activities \(A_i\) and \(A_j\), then \(A_j\) will have to be processed after \(A_i\) on \(M_u\).

- A **next edge** between two alternative activities \(A_i^u \rightarrow A_j^u\) means that if machine \(M_u\) is chosen for both activities \(A_i\) and \(A_j\), then \(A_i\) will have to be processed directly after \(A_i\) on \(M_u\). No activity may be processed on \(M_u\) between \(A_i\) and \(A_j\).

The first role of the precedence graph is to incrementally maintain the closure of this graph when new edges or vertices are inserted, \(i.e.,\) to deduce new edges given the ones already present in the graph. The following five rules [137] are used by the precedence graph:

1. If \(A_i^u \rightarrow A_j^u\), \(A_j^u \rightarrow A_i^u\), and \(A_i^u\) surely contributes then \(A_j^u\) does not contribute (Incompatibility rule).
2. If $A_u^i \rightarrow A_u^j$, $A_u^j \rightarrow A_u^k$, and $A_u^k$ surely contributes then $A_u^i \rightarrow A_u^k$ (Transitive closure through contributor).

3. If $A_u^i \sim A_u^j$, $A_u^j \rightarrow A_u^k$, and $A_u^k$ surely contributes then $A_u^i \rightarrow A_u^k$ (Next-edge closure on the left).

4. If $A_u^i \sim A_u^j$, $A_u^j \rightarrow A_u^k$, and $A_u^k$ surely contributes then $A_u^i \rightarrow A_u^k$ (Next-edge closure on the right).

5. If for all $A_u^i$ either $A_u^i \rightarrow A_u^j$ or $A_u^j \rightarrow A_u^i$ then $A_u^i \sim A_u^j$ (Next-edge finding).

New edges are added on the precedence graph $G_u$ by the scheduling constraints (precedence and resource constraints) and by the route optimization constraint (whenever a variable $next_i$ is bound a new next-edge is added). Besides computing the incremental closure, the precedence graph also incrementally maintains the set of activities that are possibly next to a given activity $A_u^i$ given the current topology of $G_u$. As such it allows to effectively reduce the domain of the variables $next_i$ and $prev_i$. Furthermore, the precedence graph constraint propagates the current set of precedence relations expressed on $G_u$ on the start and end variables of activities.

### 11.4 Conclusion

In this chapter constraint propagation methods related to the minimization of the number of late jobs and to the minimization of setup times and setup costs have been presented. They drastically improve the behavior of Constraint-Based Scheduling systems on problems involving these criteria. However, there are several other criteria. In particular, the total weighted tardiness is widely used in the industry but until now poor results are obtained on this problem. This constitutes a very interesting research area.

Finally, users of Constraint-Based Scheduling tools often have to define their own criteria. A research challenge is to design generic lower-bounding techniques and constraint propagation algorithms that could work for any criterion.
Chapter 12

Resolution of Disjunctive Problems

Disjunctive problems are scheduling problems where all resources are machines (hence activities on the same machine cannot overlap in time, i.e., they are in disjunction). These problems have been widely studied in the literature. In this chapter we address three problems: (1) the Job-Shop Problem where operations of jobs have to be processed in a given order by some specified machines, (2) the Open-Shop Problem where operations of the same job cannot overlap in time but can be executed in any order and (3) the Preemptive Job-Shop Problem.

12.1 Job-Shop Scheduling

The Job-Shop Scheduling Problem (JSSP) consists of \( n \) jobs that are to be executed using \( m \) machines. The benchmark problems used in our computational study are such that each job consists of \( m \) activities of given processing times to be executed in a specified order. Each activity requires a specified machine and each machine is required by a unique activity of each job. The JSSP is an NP-hard problem [108], known to be among the most difficult in this class. Many different methods have been tested. Most of them are branch and bound methods based upon a disjunctive graph [56], but other approaches have been used with some success as well: Mixed Integer Programming (MIP), genetic algorithms, simulated annealing, tabu search, etc.

First, the JSSP is an optimization problem. The goal is to determine a solution with minimal makespan and prove the optimality of the solution. The makespan is represented as an integer variable criterion constrained to be greater than or equal to the end of any activity. Several strategies can be considered to minimize the value of that variable, e.g., iterate on the possible values, either from the lower bound of its domain up to the upper bound (until one solution is found), or from the upper bound down to the lower bound (determining each time whether there still is a solution). In our experiments, the dichotomizing algorithm of Section 7.2.5 is used.

12.1.1 Branching Scheme

A branching procedure with constraint propagation at each node of the search tree (including disjunctive constraint propagation and Edge-Finding as described in Section 8.1.2 and Section 8.1.3) is used to determine whether the problem with makespan at most \( D \) has a solution. We rely on the fact that in order to obtain a solution it is sufficient to order the jobs on the machines. So the basic structure of this algorithm is as follows:

1. Select a resource among the resources on which the activities are not fully ordered.

2. Select an activity to execute first among the unordered activities that require the chosen resource. Post the corresponding precedence constraints. Keep the other activities as alternatives
3. Iterate step 2 until all the activities that require the chosen resource are ordered.

4. Iterate steps 1 to 3 until all the activities on all resource are ordered.

Scheduling problems are generally such that resources are not equally loaded. Some resources are, over some periods of time, more relied upon than others. These resources are often called “critical”. Their limited availability is a factor which prevents the reduction of a project cost or duration. It is, in general, very important to schedule critical resources first, in order to optimize the use of these resources without being bound by the schedule of other resources. A standard way to measure the criticality of a resource consists of comparing the “demand” for the resource to its availability (“supply”) over a specific period of time. Here, for example, the time period under consideration may run from the earliest release date of the activities to order, to the largest deadline. As the capacity of the resource is 1 at all times, the supply over this time interval is the length of the interval. The demand over the interval is the sum of the processing times of the activities to execute. Criticality is then defined as the difference between demand and supply. The main interest of ordering all the activities of the critical resource first is that when all these activities are ordered, there is very little work left to do because constraint propagation has automatically ordered activities on the other resources.

The next step requires the selection of the activity to schedule first. We choose the activity with the earliest release date; in addition, the activity with the smallest latest start time is chosen when two or several activities share the same release date.

Variants of this branch and bound procedure have been widely used in the literature [19, 37, 35, 44, 62, 63, 67, 78, 163, 177, 173, 180, 185] and have shown to be very efficient. Instances of the JSSP with up to 10 jobs and 10 machines can be solved within a few minutes of CPU time.

### 12.1.2 Computational Results

Table 12.1 gives the results obtained with the simple algorithm described above on the ten 10*10 JSSP instances used in the computational study of [8]. The columns “BT” and “CPU” give the total number of backtracks and CPU time needed to find an optimal solution and prove its optimality. Columns “BT(pr)” and “CPU(pr)” give the number of backtracks and CPU time needed for the proof of optimality. All CPU times are given in seconds on a 200 MHz PC.

Table 12.1: Results on ten 10*10 instances of the JSSP

This simple algorithm can easily be improved, as shown in the above references. In particular, recent algorithms incorporate “Shaving” techniques [63, 163, 180, 194] as described in the next section. Moreover, complex constraint propagation methods that take (partially) into account precedence relations between activities have shown to be extremely powerful. The best techniques available so far [179, 204, 205] allow to prove the optimality of all 10*10 instances in less than 30 seconds of CPU time.
12.2 Open-Shop Scheduling

The Open-Shop Scheduling Problem (OSSP) consists of a set of \( n \) jobs \( \{J_1, \ldots, J_n\} \) that have to be scheduled on \( m \) parallel identical machines \( M_1, \ldots, M_m \). A job consists of a set of operations with a given machine and processing time. Operations of the same job cannot overlap in time. The goal is to find a schedule with minimal makespan. The OSSP is NP-hard and has been shown to be very hard to solve in practice.

In our Constraint-Based Scheduling model, the Open-Shop Problem is modeled as a set of activities \( A_{ij} \) with given processing times \( p_{ij} \). Each activity \( A_{ij} \) requires two resources representing the machine on which the activity is executed and the job \( J_i \) (since activities of the same job cannot overlap).

As for the JSSP, a minimal makespan solution can be found by a dichotomizing search. At each iteration, we solve the resulting decision problem, i.e., determine a solution with makespan lower than or equal to some value \( D \) or prove that no such solution exists.

12.2.1 Branching Scheme

The same branching scheme as for the JSSP is used to solve each decision variant of the OSSP. On top of this, we use a simple dominance relation to reduce the search space. Consider a solution of the OSSP and let us define the symmetric counterpart of this schedule (start each activity \( A_{ij} \) at time \( t'_{ij} = \text{makespan} - (t_{ij} + p_{ij}) \), where \( t_{ij} \) is the starting time of activity \( A_{ij} \) on the initial schedule. It is easy to prove that the symmetric schedule is still valid. So we can arbitrary pick any activity \( A_{ij} \) and impose, a priori, that it executes mostly in the first half of the schedule:

\[
\text{start}(A_{ij}) \leq \left\lfloor \frac{\text{makespan} - p_{ij}}{2} \right\rfloor
\]

An interesting question is how to determine the activity on which this domain reduction is to be achieved. To estimate the impact of this domain reduction, it is “tried”. For each activity \( A_{ij} \), we compute the sum of the domain sizes of the variables of the problem when \( A_{ij} \) is constrained to execute mostly in the first half of the schedule. This is, we hope, a rough estimation of the remaining hardness of the problem. The activity that minimizes this sum is picked.

12.2.2 More and More Propagation: Shaving

Global operations also called “Shaving” have been used by Carlier and Pinson [63] and by Martin and Shmoys [163] to reduce the search space for the JSSP. This mechanism is also valid for any disjunctive problem (e.g., Dorndorf, Pesch and Phan-Huy [87] show in their computational study of the OSSP that it can be of great practical interest). The basic idea is very simple. At each node of the search tree and for each activity \( A_i \), the earliest date \( x_i \) at which the activity can be scheduled without triggering a contradiction is computed. This basically consists of

1. iteratively trying a start time for the activity \( A_i \),
2. propagating the consequence of this decision thanks to the edge-finding bounding technique, and
3. verifying that no contradiction has been detected.

The earliest date \( x_i \) is of great interest since it can serve to adjust the release date of the activity. A dichotomizing procedure can be used to determine the date \( x_i \). It decreases both the theoretical and the practical complexities of the algorithm.

Several extensions of this mechanism are proposed by Péridy [180]. The underlying idea is to impose a decision (e.g., a starting time for a given activity) and to exploit the consequences of this decision in more or less complex algorithms to obtain global information on the instance.
12.2.3 Computational Results

On top of the dominance relation and of the classical disjunctive branching scheme, we also apply two propagation features used by Dorndorf, Pesch and Phan-Huy [87] in their computational study of the Open-Shop:

- **Not-First, Not-Last** propagation (cf., Section 8.1.4) and
- **Shaving**, as defined in Section 12.2.2.

To evaluate the efficiency of these propagation techniques, the branch and bound procedure has been run on 132 instances of the OSSP (52 instances from [41] and 80 instances from [114]). These instances contain up to 100 jobs. Four variants of the algorithm have been tested:

- **STD**. Propagation includes the disjunctive constraint, Edge-Finding and the Not-First and Not-Last rules applied only to the maximal set of unordered activities.
- **SH**. Earliest start times and latest end times are shaved using the STD propagation.
- **NFNL**. Similar to STD but the Not-First and Not-Last rules are applied to all possible subsets.
- **SH+NFNL**. Both Shaving and Not-First Not-Last propagation are used.

Within a one hour time-limit, 122 instances can be solved by any of the procedures that use Shaving. These results compare well to more complex procedures such as [41]. Dorndorf, Pesch and Phan-Huy [87] report better computational results thanks to an improved version of the dichotomic search.

With STD and NFNL, 108 and 107 instances only are solved respectively. Figure 12.1 reports the number of instances solved (Nb Solved) within a given time limit (CPU) for the four different versions of the search procedure.

![Figure 12.1: Number of OSSP instances solved in a given amount of CPU time](image)

As noticed in [87], Shaving seems to be a key feature for solving the OSSP. However, it appears that the cost of applying systematically the NFNL rules is not balanced by the corresponding reduction of the search space. Applying the NFNL rules to the maximal subset can be done in linear time and seems to capture most of the propagation information.
As noticed by several researchers, the OSSP is harder to solve in practice than the JSSP. While all 10*10 instances of the JSSP are solved within a few second of CPU time, a 7*7 OSSP instance from [41] is still open!

Several techniques have been recently designed for the Open-Shop. In particular, we have not used, until now, any “intelligent backtracking” rule such as the one proposed by Guéret, Jussien and Prins [115]. We are quite confident that, together with powerful propagation techniques such as Shaving, this could lead to a drastic improvement for the resolution of the OSSP.

12.3 Preemptive Job-Shop Scheduling

The Preemptive Job-Shop Scheduling Problem (PJSSP) is the variant of the Job-Shop Scheduling Problem (JSSP) in which all activities are interruptible. Given are a set of jobs and a set of machines. Each job consists of a set of activities to be processed in a given order. Each activity is given an integer processing time and a machine on which it has to be processed. A machine can process at most one activity at a time. Activities may be interrupted at any time, an unlimited number of times. The problem is to find a schedule, i.e., a set of integer execution times for each activity, that minimizes the makespan, i.e., the time at which all activities are finished. We remark that the total number of interruptions of a given activity is bounded by its processing time minus 1. The PJSSP is NP-hard in the strong sense [108].

Formally, a start time variable \( start(A_i) \), an end time variable \( end(A_i) \), an integer processing time \( p_i \) and a set variable \( set(A_i) \) are associated with each activity \( A_i \). The set variable \( set(A_i) \) represents the set of times at which \( A_i \) executes, \( start(A_i) \) represents the time at which \( A_i \) starts, \( end(A_i) \) the time at which \( A_i \) ends, and \( p_i \) the number of time units required for \( A_i \). An additional variable, \( makespan \), represents the makespan of the schedule. The following constraints apply:

- For every activity \( A_i \), \( p_i = |set(A_i)| \).
- For every activity \( A_i \), \( start(A_i) = \min_{t \in set(A_i)}(t) \) and \( end(A_i) = \max_{t \in set(A_i)}(t + 1) \). This implies \( end(A_i) \geq start(A_i) + p_i \). We remark that in a given solution we have \( end(A_i) = start(A_i) + p_i \) if and only if \( A_i \) is not interrupted.
- For every job \( J = (A_1, A_2, \ldots, A_m) \) and every \( i \) in \( \{1, 2, \ldots, m - 1\} \), \( end(A_i) \leq start(A_{i+1}) \).
- For every machine \( M \), if \( \Omega_M \) denotes the set of activities to be processed on \( M \), then, for every pair of activities \( (A_i, A_j) \) in \( \Omega_M \), \( set(A_i) \) and \( set(A_j) \) are disjoint.
- For every activity \( A_i \), \( 0 \leq start(A_i) \).
- For every activity \( A_i \), \( end(A_i) \leq makespan \).

Constraint propagation techniques for all these types of constraints have been presented in Chapters 1 and 2.

As seen in Section 12.1, the most successful branch and bound approaches for the non-preemptive JSSP consist of ordering the set of activities \( \Omega_M \) which require the same machine \( M \). At each node, a machine \( M \) and a set \( \Omega \subseteq \Omega_M \) are selected. For each activity \( A_i \) in \( \Omega \), a new branch is created where \( A_i \) is constrained to execute first (or last) among the activities in \( \Omega \). This decision is then propagated, through some variant or extension of the Edge-Finding constraint propagation technique. For the PJSSP, this branching scheme is not valid since activities are interruptible, and thus cannot just be ordered. This has a dramatic impact on the size of the search space. Let us consider, for example, 4 activities, each of processing time 10, to be executed on the same machine: there are \( 40!/(10!)^4 = 4705360871073570227520 \) possible orders of the 40 activity time units in the PJSSP, to be compared with \( 4! = 24 \) orders of the 4 activities in the JSSP. Considering only one of these activities \( A_i \) with earliest start time 0 and latest end time 40, the number of possible values for \( set(A_i) \) is \( 40!/(10! \times 30!) = 847660528 \) in the PJSSP, to be compared with \( 40 - 10 = 30 \) possible
values for \( start(A_i) \) in the JSSP. As often in CP, the first and foremost thing to do (besides constraint propagation) to solve the PJSSP is to establish a dominance relation allowing the elimination of dominated solutions.

Section 12.3.1 presents such a dominance relation. Section 12.3.2 shows how it enables the definition of a simple depth first search algorithm for the Preemptive Job-Shop Scheduling Problem. Section 12.3.3 presents and compares different heuristic variants of this algorithm (still based on depth first search) and Section 12.3.4 examines the replacement of depth first search with various forms of limited discrepancy search [116].

### 12.3.1 Dominance Relation

The dominance relation introduced in this section allows the design of branching schemes which in a sense “order” the activities that require the same machine. The basic idea is that it does not make sense to let an activity \( A_i \) interrupt an activity \( A_j \) by which it was previously interrupted. In addition, \( A_i \) shall not interrupt \( A_j \) if the successor of \( A_i \) (in its job) starts after the successor of \( A_j \). The following definitions and theorems provide a formal characterization of the dominance relation.

**Definition 30.** For any schedule \( S \) and any activity \( A_i \), we define the “due date of \( A_i \) in \( S \)” \( d_S(A_i) \) as:

- the makespan of \( S \) if \( A_i \) is the last activity of its job;
- the start time of the successor of \( A_i \) (in its job) otherwise.

**Definition 31.** For any schedule \( S \), an activity \( A_k \) has priority over an activity \( A_i \) in \( S \) \((A_k <_S A_i)\) if and only if either \( d_S(A_k) < d_S(A_i) \) or \( d_S(A_k) = d_S(A_i) \) and \( k \leq l \). Note that \( <_S \) is a total order.

**Proposition 88.** For any schedule \( S \), there exists a schedule \( J(S) \) such that:

1. \( J(S) \) meets the due dates: \( \forall A_i, \) the end time of \( A_i \) in \( J(S) \) is at most \( d_S(A_i) \).
2. \( J(S) \) is “active”: For any machine \( M \) and any time point \( t \), if some activity \( A_i \in \Omega_M \) is available at time \( t \), \( M \) is not idle at time \( t \) (where “available” means that the predecessor of \( A_i \) is finished and \( A_i \) is not finished).
3. \( J(S) \) follows the \( <_S \) priority order: \( \forall M, \forall t, \forall A_k \in \Omega_M, \forall A_i \in \Omega_M, A_i \neq A_k, \) if \( A_k \) executes at time \( t \), either \( A_i \) is not available at time \( t \) or \( A_k <_S A_i \).

**Proof.** We construct \( J(S) \) chronologically. At any time \( t \) and on any machine \( M \), the available activity that is the smallest (according to the \( <_S \) order) is scheduled. \( J(S) \) satisfies properties 2 and 3 by construction. Let us suppose \( J(S) \) does not satisfy property 1. Let \( A_i \) denote the smallest activity (according to \( <_S \)) such that the end time of \( A_i \) in \( J(S) \) exceeds \( d_S(A_i) \). We claim that:

- the schedule of \( A_i \) is not influenced by the activities \( A_k \) with \( A_i <_S A_k \) (by construction);
- for every activity \( A_k <_S A_i \), the time at which \( A_k \) becomes available in \( J(S) \) does not exceed the time at which \( A_k \) starts in \( S \) (because the predecessor of \( A_k \) is smaller than \( A_i \)).

Let \( M \) be the machine on which \( A_i \) executes. The activities \( A_k \in \Omega_M \) such that \( A_k <_S A_i \) are, in \( J(S) \), scheduled in accordance with Jackson’s rule (cf., [62]) applied to the due dates \( d_S(A_k) \). Since \( d_S(A_i) \) is not met, and since Jackson’s rule is guaranteed to meet due dates whenever it is possible to do so, we deduce that it is impossible to schedule the activities \( A_k \in \Omega_M \) such that \( A_k <_S A_i \) between their start times in \( S \) and their due dates in \( S \). This leads to a contradiction, since in \( S \) these activities are scheduled between their start times and their due dates.

We call \( J(S) \) the “Jackson derivation” of \( S \). Since the makespan of \( J(S) \) does not exceed the makespan of \( S \), at least one optimal schedule is the Jackson derivation of another schedule. Thus, in the search for an optimal schedule, we can impose the characteristics of a Jackson derivation to the schedule under construction. This results in a significant reduction of the size of the search space.
12.3 Preemptive Job-Shop Scheduling

Job 3: executes on M2 (duration= 5), on M1 (duration= 2) and finally on M3 (duration= 1)

Job 2: executes on M1 (duration= 2), on M3 (duration= 1) and finally on M2 (duration= 2)

Job 1: executes on M1 (duration= 3), on M2 (duration= 3) and finally on M3 (duration= 5)

Schedule $S$

Schedule $J(S)$

Figure 12.2: A preemptive schedule and its Jackson derivation

12.3.2 Branching Scheme

The dominance relation of the previous section led us to develop the following branching scheme (which heavily exploits the dominance relation):

1. Let $t$ be the earliest date such that there is an activity $A_i$ available (and not scheduled yet) at $t$.
2. Compute $K$, the set of activities available at $t$ on the same machine than $A_i$.
3. Compute $NDK$, the set of activities which are not “dominated” in $K$ (as explained below).
4. Select an activity $A_k$ in $NDK$ (e.g., the one with the smallest latest end time). Schedule $A_k$ to execute at $t$. Propagate the decision and its consequences according to the dominance relation (as explained below). Keep the other activities of $NDK$ as alternatives to be tried upon backtracking.
5. Iterate until all the activities are scheduled or until all alternatives have been tried.

Needless to say, the power of this branching scheme highly depends on the rules that are used to eliminate “dominated” activities in step 3 and propagate “consequences” of the choice of $A_k$ in step 4. The dominance relation is exploited as follows:

- Whenever $A_k \in \Omega_M$ is chosen to execute at time $t$, it is set to execute either up to its earliest possible end time or up to the earliest possible start time of another activity $A_l \in \Omega_M$ which is not available at $t$.

- Whenever $A_k \in K$ is chosen to execute at time $t$, any other activity $A_l \in K$ can be constrained not to execute between $t$ and the end of $A_k$. At times $t' > t$, this reduces the set of candidates for execution ($A_l$ is “dominated” by $A_k$, hence not included in $NDK$). In step 4, “redundant” constraints can also be added: $end(A_k) + rp_l(A_l) \leq end(A_l)$, where $rp_l(A_l)$ is the remaining processing time of $A_l$ at time $t$; $end(A_k) \leq start(A_l)$ if $A_l$ is not started at time $t$.

- Let $A_k \in \Omega_M$ be the last activity of its job. Let $A_l \in \Omega_M$ be another activity such that either $l < k$ or $A_l$ is not the last activity of its job. Then, if $A_l$ is available at time $t$, $A_k$ is not candidate for execution at time $t$ ($A_k$ is dominated by $A_l$).

The proof that these reductions of the search space do not eliminate all optimal schedules follows from the fact that $J(S)$ schedules are dominant. Indeed, in a $J(S)$ schedule, (i) an activity cannot be interrupted unless a new activity becomes available on the same resource, (ii) an activity $A_k$
cannot execute when another activity $A_l$ is available, unless $A_k <_S A_l$, and (iii) we cannot have $A_k <_S A_l$ if $A_k$ is the last activity of its job and either $A_l$ is not the last activity of its job or $l < k$.

This branching scheme is integrated in the dichotomizing algorithm of Section 7.2.5. The resulting algorithm has been tested using different constraint propagation techniques for the resource constraints: Time-Tables (TT), Edge-Finding (EF) and network flows (SCF, AEC and GUTB). Computational results presented in [150] show that both Edge-Finding and the GUTB algorithm allow the resolution of difficult problems with 100 activities. In particular, five of the ten $10 \times 10$ ($i.e.$, 10 machines $\times$ 10 jobs = 100 activities) instances used by Applegate and Cook [8] in their computational study of the (non-preemptive) Job-Shop Problem have been solved to optimality in a few hours of CPU time using GUTB. The Edge-Finding algorithm enabled the exact resolution of all of these ten instances with CPU time varying from 1 minute to 27 hours (3.4 hours on average) on a 200 MHz PC.

12.3.3 Heuristic Algorithms

Several variants of the previous algorithm can be designed to search for “good” rather than optimal solutions. Different algorithms shall then be compared not with respect to the time needed to solve the optimization problem ($i.e.$, find an optimal solution and prove it is optimal), but with respect to the value of the best solution found after a given amount of time. Several changes to the previous algorithm have been explored from this point of view.

Let us first consider the course of action to follow when a new solution has been found by the branch and bound algorithm. The alternative is either to “continue” the search for a better solution in the current search tree (with a new constraint stating that the makespan must be smaller than the current one) or to “restart” a brand new branch and bound search (with the same additional constraint). The main advantage of restarting the search is that the heuristic choices can rely on the result of the new propagation (based on the new upper bound), which shall lead to a better exploration of the search tree. The drawback is that parts of the new search tree may have been explored in a previous iteration, which results in redoing the same unfruitful work.

As far as the PJSSP is concerned, the restart strategy brings another point of flexibility, concerning the selection of an activity $A_k$ in NDK. A basic strategy consists of selecting $A_k$ according to a specific heuristic rule. Selecting the activity with the earliest deadline seems reasonable since it corresponds to the rule which optimally solves the Preemptive One-Machine Problem (see, for instance, [62]). However, one can also rely on the best schedule $S$ computed so far: selecting the activity $A_k$ with minimal $d_S(A_k)$ should help to find a better schedule when there exists one that is “close” to the previous one.

In addition, the Jackson derivation operator $J$ and its symmetric counterpart $K$ can be used to improve the current schedule. Whenever a new schedule $S$ is found, derivations $J$ and $K$ can be applied to improve the current schedule prior to restarting the search. Several strategies can be considered, e.g., apply only $J$, apply only $K$, apply a sequence of $J$’s and $K$’s. The following strategy appears to work well on average:

- compute $J(S)$ and $K(S)$;
- replace $S$ with the best schedule among $J(S)$ and $K(S)$, if this schedule is strictly better than $S$ ($J(S)$ is chosen if $J(S)$ and $K(S)$ have the same makespan);
- if $S$ has been replaced by either $J(S)$ or $K(S)$, iterate.

Globally, this leads to five strategies based on the previous depth first search algorithm: DFS-C-E, DFS-R-E, DFS-R-E-JK, DFS-R-B and DFS-R-B-JK, where C, R, E, B, JK stand respectively for “Continue search in the same tree”, “Restart search in a new tree”, “select activities according to the Earliest deadline rule”, “select activities according to their position on the Best schedule met so far” and “apply JK derivation operators”.

Table 12.2 provides the results obtained on the preemptive variant of the ten $10 \times 10$ instances used in [8]. Two constraint propagation techniques are considered: Time-Table as a fast algorithm that does not prune much, and Edge-Finding as a constraint propagation algorithm that requires
more time but enables better pruning of the search tree. Each line of the table corresponds to a “constraint propagation + search” combination, and provides the mean relative error (MRE, in percentage) obtained after 1, 2, 3, 4, 5, and 10 min of CPU time. For each instance, the relative error is computed as the difference between the obtained makespan and the optimal value, divided by the optimal value. The MRE is the average relative error over the ten instances.

Table 12.3 provides the results obtained on the thirteen instances used by Vaessens, Aarts, and Lenstra [213] to compare local search algorithms for the non-preemptive Job-Shop Problem. As these instances differ in size, we allocated to each instance an amount of time proportional to the square of the number of activities in the instance. This means that column 1 corresponds to the allocation of 1 min to a $10 \times 10$ problem, 15 sec for a $10 \times 5$ problem, 4 min for a $20 \times 10$ problem, etc. We used the square of the number of activities, because the time spent per node appeared to be approximately linear in the number of activities [151], and the number of decisions necessary to construct a schedule (i.e., the depth of the search tree) is also proportional to the number of activities (hence the time necessary to reach the first solution tends to increase as the square of the number of activities). To our knowledge, five of the thirteen instances are, in the preemptive case, open (and we have been unable to solve them with the exact algorithm). For these instances, we applied a variant of Edge-Finding and Shaving (cf., Section 12.2.2) to obtain a lower bound, and thus estimate the relative error.

Table 12.3: DFS results on the thirteen instances used in [213]

These tables show that the use of the Edge-Finding technique enables the generation of good solutions in a limited amount of time and that the DFS-R-B-JK variant clearly outperforms the other algorithms, especially when the Edge-Finding technique is used.
Limited Discrepancy Search (LDS) [116] is an alternative to the classical depth first search algorithm. This technique relies on the intuition that heuristics make few mistakes through the search tree. Thus, considering the path from the root node of the tree to the first solution found by a DFS algorithm, there should be few “wrong turns” (i.e., few nodes which were not immediately selected by the heuristic). The basic idea is to restrict the search to paths which do not diverge more than \( w \) times from the choices recommended by the heuristic. When \( w = 0 \), only the leftmost branch of the search tree is explored. When \( w = 1 \), the number of paths explored is linear in the depth of the search tree, since only one alternative turn is allowed for each path. Each time this limited search fails, \( w \) is incremented and the process is iterated, until either a solution is found or it is proven that there is no solution. It is easy to prove that when \( w \) gets large enough, LDS is complete. At each iteration, the branches where the discrepancies occur close to the root of the tree are explored first (which makes sense when the heuristics are more likely to make mistakes early in the search).

Several variants of the basic LDS algorithm can be considered:

- When the search tree is not binary, it can be considered that the \( i \)th best choice according to the heuristic corresponds either to 1 or to \((i - 1)\) discrepancies. In the following, we consider it represents \((i - 1)\) discrepancies because the second best choice is often much better than the third, etc. In practice, this makes the search tree equivalent to a binary tree where each decision consists of either retaining or eliminating the best activity according to the heuristic.

- The first iteration may correspond either to \( w = 0 \) or to \( w = 1 \). In the latter case, one can also modify the order in which nodes are explored during the first iteration (i.e., start with discrepancies far from the root of the tree). The results reported below are based on a LDS algorithm which starts with \( w = 0 \).

- Korf proposed an improvement based on an upper bound on the depth of the search tree [131]. In our case, the depth of the search tree can vary a lot from a branch to another (even though it remains linear in the size of the problem), so we decided not to use Korf’s variant. This implies that, to explore a complete tree, our implementation of LDS has a very high overhead over DFS.

- Walsh proposed another variant called “Depth-bounded Discrepancy Search” (DDS), in which any number of discrepancies is allowed, provided that all the discrepancies occur up to a given depth [216]. This variant is recommended when the heuristic is very unlikely to make mistakes in the middle and at the bottom of the search tree (i.e., when almost all mistakes occur at low depth). We tried both LDS and DDS, and decided to focus on LDS, which appears to perform better. Some computational results with DDS are provided below.

Table 12.4 provides the results obtained by the five LDS variants, LDS-C-E, LDS-R-E, LDS-R-E-JK, LDS-R-B and LDS-R-B-JK, on the ten instances used by Applegate and Cook. Table 12.5 provides the results for the thirteen instances used by Vaessens, Aarts, and Lenstra. Figures 12.3 and 12.4 present the evolution of the mean relative error for the eight “constraint propagation + search” combinations in which the \( J \) and \( K \) operators are used. The combination of the Edge-Finding constraint propagation algorithm with LDS-R-B-JK appears to be the clear winner.

Tables 12.6 and 12.7 provide the results obtained using DFS and variants of LDS with the Edge-Finding constraint propagation algorithm and the R-E-JK and R-B-JK heuristic search strategies. In these tables, LDS\( N \) and DDS\( N \) refer to the application of the LDS and DDS principles on the \( N \)-ary tree, where each son of a node corresponds to scheduling one candidate activity on the corresponding machine. LDS and DDS (without the \( N \)) correspond to the application of LDS and

186 Resolution of Disjunctive Problems

Figure 12.4: Evolution of the mean relative error on the thirteen instances used in [213]

DDS to the binary tree in which each decision consists of either scheduling or postponing the best candidate. Figure 12.5 illustrates the difference between the five algorithms, DFS, LDS, LDS\textsuperscript{N}, DDS, and DDS\textsuperscript{N}, on a ternary tree of depth three. “ITE” shows at which iteration each leaf of the tree is attained (starting with iteration number 0) and “ORD” shows in which order the leaves are visited. It shall be noted that, to explore a complete tree, LDS and DDS have a high overhead over DFS. Hence, LDS and DDS must quickly repair the bad decisions to beat DFS. LDS\textsuperscript{N} and DDS\textsuperscript{N} have a much smaller overhead on a complete tree. Hence, their performance is less dependent on the quick repair of the “worst” decisions. However, in LDS\textsuperscript{N} and DDS\textsuperscript{N}, the 2nd, 3rd, \ldots and \textit{N}th sons of a node are considered equal, which can lead to the early exploration of unpromising branches.

Table 12.6: LDS variants on the ten instances used in [8]

LDS on the binary tree appears to be the best overall alternative. LDS\textsuperscript{N}-R-B-JK also performs well, in particular in Table 12.7. By contrast, DDS and DDS\textsuperscript{N} do not perform well. In particular, DDS-R-B-JK and DDS\textsuperscript{N}-R-B-JK do not perform better than DFS-R-B-JK in Table 12.6 and for the first values of the time factor in Table 12.7.

Edge-Finding appears as the most crucial of the techniques we used to provide good solutions to the PJSSP. On the 13 instances used in [213], all the algorithms that use Edge-Finding perform better than all the algorithms that do not. Tables 12.8 and 12.9 provide the average gains in MRE over the 8 DFS-R-\textsuperscript{*} and LDS-R-\textsuperscript{*} scenarios, when each of the other techniques is added. When Edge-Finding is not used, LDS appears as the second most important technique. When Edge-Finding is used, the contributions of the different techniques are closer one to the other. This confirms the observation in [30] that LDS appears to help the weaker algorithms to a greater extent than the

Chapter 13

Cumulative Scheduling Problems

Many industrial scheduling problems are variants, extensions or restrictions of the “Resource-Constrained Project Scheduling Problem”. Given (i) a set of resources with given capacities, (ii) a set of non-interruptible activities of given processing times, (iii) a network of precedence constraints between the activities, and (iv) for each activity and each resource the amount of the resource required by the activity over its execution, the goal of the RCPSP is to find a schedule meeting all the constraints whose makespan (i.e., the time at which all activities are finished) is minimal. The decision variant of the RCPSP, i.e., the problem of determining whether there exists a schedule of makespan smaller than a given deadline, is NP-hard in the strong sense [108].

In particular, the Hybrid Flow-Shop Scheduling Problem (HFSSP) is a special case of the RCPSP. To precisely define the Hybrid Flow-Shop Scheduling Problem, assume that a set \( \{J_1, \ldots, J_n\} \) of \( n \) simultaneously available jobs must be sequentially processed on a set of \( s \) stages \( S = \{1, 2, \ldots, s\} \). Each job is processed first at stage 1, then at stage 2, \ldots, and finally at stage \( s \). At stage \( j \), \( m_j \) identical parallel machines are available. Each job \( J_i \) can only be processed on one machine at a time and consists of \( s \) operations \( O_{i1}, O_{i2}, \ldots, O_{is} \). An operation \( O_{ij} \) has a processing time \( p_{ij} \) and has to be processed without preemption on only one of the machines at stage \( j \). The objective is, again, to find a schedule which minimizes the maximum completion time.

It is obvious that the HFSSP can be seen as a RCPSP where each operation is modeled by an activity and where each stage \( j \) is modeled by a resource of capacity \( m_j \). Resource requirements are unitary, and the precedence network is made of \( n \) chains representing the jobs. Notice that if there are only two stages and if there is a single machine at each of the two stages, then the above Hybrid Flow-Shop Problem is solvable in \( O(n \log n) \) time by the well-known algorithm developed by Johnson [127]. Other than this case, the Hybrid Flow-Shop Scheduling Problem is NP-hard in the strong sense even if there are only two available machines at one of the stages [121].

The aim of this computational study is to test the efficiency of the constraint propagation schemes described in the previous chapters and also to investigate one particular dimension along which problems differ. Within the cumulative scheduling class, we distinguish between highly disjunctive and highly cumulative problems: a scheduling problem is highly disjunctive when many pairs of activities cannot execute in parallel on the same resource; conversely, a scheduling problem is highly cumulative when many activities can execute in parallel on the same resource. To formalize this notion, we introduce the disjunction ratio, i.e., the ratio between a lower bound of the number of pairs of activities which cannot execute in parallel and the overall number of pairs of distinct activities. A simple lower bound of the number of pairs of activities which cannot execute in parallel can be obtained by considering pairs \( \{A_i, A_j\} \) such that either there is a chain of precedence constraints between \( A_i \) and \( A_j \), or there is a resource constraint which is violated if \( A_i \) and \( A_j \) overlap in time. The disjunction ratio can be defined either globally (considering all the activities of a given problem instance) or for each resource \( R \) by limiting the pairs of activities to those that require at least one unit of \( R \). The disjunction ratio of a resource of capacity 1 is equal to 1. The disjunction ratio of a cumulative resource varies between 0 and 1, depending on the precedence constraints and on the amounts of capacity that are required to execute the activities. In particular,
the ratio is equal to 0 when there is no precedence constraint and no activity requires more than half of the resource capacity. When each stage is made of several machines, the disjunction ratio of the HFSSP is low due to the unitary resource requirements.

Needless to say, the disjunction ratio is only one of a variety of indicators that could be associated with scheduling problem instances. For example, the precedence ratio (also known as order strength [164] flexibility ratio, and density [85]), i.e., the ratio between the number of pairs of activities which are ordered by precedence constraints and the overall number of pairs of distinct activities, is also important (a high precedence ratio makes the problem easier). Although some researchers, e.g., [130], have worked on such indicators, we believe much more work is necessary to discover which ones are appropriate for designing, selecting, or adapting CP techniques with respect to the characteristics of a given problem.

In the following, we explore the hypothesis that the disjunction ratio is an important indicator of which techniques shall be applied to a cumulative scheduling problem. With this distinction in mind, we introduce several new techniques to solve the RCPSP. They will be also applied to the HFSSP.

Section 13.1 presents our general approach to the resolution of the RCPSP. Sections 13.2 and 13.3 respectively present some computational results on the HFSSP and on the RCPSP. They confirm that the techniques we use exhibit different behaviors on problems with different disjunction ratios.

### 13.1 General Framework

The aim of this section is to present a list (by no means exhaustive) of possible “ingredients” that can be incorporated in a CP approach to the RCPSP. We limit the discussion to the standard RCPSP. However, some of the techniques we propose also apply to extensions of the RCPSP, such as problems with interruptible activities.

First, the RCPSP is an optimization problem. The goal is to determine a solution with minimal makespan and prove the optimality of the solution. As for the Job-Shop, we represent the makespan as an integer variable constrained to be greater than or equal to the end of any activity. Again we use the dichotomizing algorithm of Section 7.2.5.

A branching procedure with constraint propagation at each node of the search tree is used to determine whether the problem with makespan at most $D$ accepts a solution. As shown in the literature, there are many possible choices regarding the amount of constraint propagation that can be made at each node. [57, 83, 84] use simple bounding techniques compared to the more complex constraint propagation algorithms described in the previous chapters. Performing more constraint propagation serves two purposes: first, detect that a partial solution at a given node cannot be extended into a complete solution with makespan lower than or equal to $D$; second, reduce the domains of the start and end variables, thereby providing useful information on which variables are the most constrained. However, complex constraint propagation algorithms take time to execute, so the cost of these algorithms may not always be balanced by the subsequent reduction of search.

The deductive techniques for cumulative resources have been tested on the RCPSP and on the HFSSP. Computational results show that it is worth using such techniques when the disjunction ratio is low. Artificially adding “redundant” constraints, i.e., constraints that do not change the set of solutions, but propagate in a different way, is another method for improving the effectiveness of constraint propagation. For example, [57, 58, 59] present branch and bound algorithms for the RCPSP which rely on the generation of redundant resource constraints. If $S$ is a set of activities and $m$ an integer value, and if for any subset $s$ of $S$ such that $|s| > m$, the activities of $s$ cannot all overlap, then the following resource constraint can be added: “Each activity of $S$ requires exactly one unit of a new (artificial) resource of capacity $m$”.

Besides constraint propagation, a branching solution search procedure is also characterized by:

- **The types of decisions that are made at each node.** Most search procedures for the RCPSP chronologically build a schedule, from time 0 to time $v$. At a given time $t$, Demeulemeester and Herroelen [83] schedule a subset of the available activities; other subsets are tried
upon backtracking. The main interest of this strategy is that some resource can be maximally
used at time $t$, prior to proceed to a time $t' > t$. However, there may be many subsets to
try upon backtracking, especially if the problem is highly cumulative. An example of non-
chronological scheduling strategy is given by Carlier and Latapie [57]. Their strategy is based
on dichotomizing the domains of the start variables: at each node, the lower or the upper half
of the domain of a chosen variable $V$ is removed and the decision is propagated. This strat-
egy may work well if there are good reasons for selecting the variable $V$, rather than another
variable (e.g., when there is a clear resource bottleneck at a given time).

- **The heuristics that are used to select which possibilities to explore first.** When a
chronological strategy is used, one can either try to “fill” the resources at time $t$ (to avoid the
insertion of resource idle time in the schedule) or select the most urgent activities among those
that are available at time $t$. When a non-chronological strategy is used, the best is to focus
first on identified bottlenecks.

- **The dominance relations that are applied to eliminate unpromising branches.** Several
dominance rules have been developed for the RCPSP (see, for example [83, 22, 23]). These
rules enable the reduction of the search to a limited number of nodes which “dominate” the
others, i.e., are guaranteed to include better schedules than the nodes that are eliminated. As
for constraint propagation, dynamically applying complex dominance rules at each node of the
search tree may prove more costly than beneficial.

- **The backtracking strategy that is applied upon failure.** Most CP tools rely on depth
first chronological backtracking. However, “intelligent” backtracking strategies can also be
applied to the RCPSP. For example, the cut-set dominance rule of Demeulemeester and Her-
roelen [83, 84] can be seen as an intelligent backtracking strategy, which consists of memorizing
search states to avoid redoing the same work twice. When backtracking, the remaining sub-
problem is saved. In the remainder of the search tree, the algorithm checks if the remaining
subproblem is not already proved unfeasible. The advantage of such techniques is that the
identified impossible problem-solving situations are not encountered twice (or are immediately
recognized as impossible). However, such techniques may require large amounts of memory to
store the intermediate search results and, in some cases, significant time for their application.

We refer to [22] for a detailed study of all these aspects of the problem-solving strategy. Our
aim is to evaluate the efficiency of the constraint propagation techniques described in the previous
chapters. For this reason, we do not generate redundant resources, we do not apply the complex
dominance rules of [83, 22, 23] and we do not use the cut-set rule. Hence the computational results
could be improved.

Our solution search procedure is based upon [152]:

1. Initialize the set of selectable activities to the complete set of activities to schedule.

2. If all the activities have fixed start and end times, a solution is found, exit. Otherwise, remove
from the set of selectable activities those activities which have fixed start and end times.

3. If the set of selectable activities is not empty, select an activity from the set (e.g., one with
smallest deadline), create a choice point for the selected activity (to allow backtracking) and
schedule the selected activity from its earliest start time to its earliest end time. Then go to
step 2.

4. If the set of selectable activities is empty, backtrack to the most recent choice point. (If there
is no such choice point, report that there is no problem solution and exit.)

5. Upon backtracking, mark the activity that was scheduled at the considered choice point as not
selectable as long as its earliest start and end times have not changed. Then go to step 2.
The correctness of this algorithm is easy to demonstrate. Indeed, the activity $A_i$ chosen at step 3 must either start at its earliest start time (and consequently end at its earliest end time) or must be postponed to start later. But starting $A_i$ later makes sense only if other activities prevent $A_i$ from starting at its earliest start time, in which case the scheduling of these other activities must eventually result (thanks to constraint propagation!) in the update of the earliest start and end times of $A_i$. Hence a backtrack from step 4 signifies that all the activities which do not have fixed start and end times have been postponed. This is absurd as in any solution the activity which will start the earliest among those which have been postponed could be set to start at its earliest start time. This is why it is correct to backtrack from step 4 up to the most recent choice point.

Several constraint propagation algorithms can be associated with each resource. Among these algorithms, the Time-Table mechanism, is systematically applied. It guarantees that, at the end of the propagation, the earliest start time of each unscheduled activity is consistent with the start and end times of all the scheduled activities (i.e., activities with bound start and end times).

13.2 Hybrid Flow-Shop Scheduling

The branch and bound procedure has been tested on 92 HFSSP instances generated by Carlier and Néron [59]. Problem size varies from 10 jobs and 5 stages, to 15 jobs and 5 stages. The machine configurations are equilibrated, i.e., all stages have the same number of available machines (3 machines at all the stages), or are almost equilibrated (3 machines at all stages, excepted the third stage in which only 2 machines are available). As reported in [59] this makes the problem extremely hard to solve in practice.

The maximum CPU time allowed to solve a given problem instance was set at 3,600 seconds. Figure 13.1 reports the number of instances solved (Nb Solved) within a given time limit (CPU) for three different versions of our search procedure:

- with EnerGetic (EG) reasoning (Left-Shift / Right-Shift),
- with Edge-Finding (EF),
- with No (N) additional propagation.

On “easy” instances (those solved in a few seconds by all methods), the cost of the more complex time-bound adjustment algorithms is not balanced by the subsequent reduction of search, and the CPU time increases. On the contrary, when instances become hard, the energetic reasoning outperform all other techniques. Within a one hour time-limit, 76 instances are solved with energetic reasoning while 74 and 66 instances only are respectively solved with Edge-Finding and with Time-Tables only.

Over the 66 instances that have been solved by all three versions of the branch and bound (EG, EF and N), the reduction of the number of backtracks is very impressive. An average of 14917 backtracks was required by the EG version of the algorithm while EF and N required respectively 150853 and 1285595 backtracks! Following these results an improved version of these algorithms, incorporating Shaving (see Section 12.2.2) and dominance rules, has been developped in [171].

13.3 Resource-Constrained Project Scheduling

The three versions of the algorithm were tested on two sets of data.

- The “KSD” set of Kolisch, Sprecher and Drexel [130], which includes 480 instances with 30 activities and 4 resources. These instances are interesting because they are classified according to various indicators, including the “resource strength,” i.e., the resource capacity, normalized so that the “strength” is 0 when for each resource $R$, $\text{cap}(R) = \max_i(\text{cap}(A_i, R))$, and the “strength” is 1 when scheduling each activity at its earliest start time (ignoring resource constraints) results in a schedule that satisfies resource constraints as well.
Figure 13.1: Number of HFSSP instances solved in a given amount of CPU time

- The “BL” set of Baptiste and Le Pape [22] which includes 40 instances with either 20 or 25 activities, and 3 resources. Each activity requires the 3 resources, with a required capacity randomly chosen between 0 and 60% of the resource capacity. 15 precedence constraints were randomly generated for problems with 20 activities; 45 precedence constraints were generated for problems with 25 activities.

The average disjunction ratios for the two sets of instances are respectively 0.56 for the KSD set and 0.33 for the BL set. As a matter of fact, the BL instances have been generated because it appeared that most of the classical instances from the literature are highly disjunctive (which is not representative of the real-life RCPSP instances that we observed).

Figures 13.2 and 13.3 provide the results obtained on the KSD and the BL sets of benchmarks with three different versions of our search procedure: with EnerGetic (EG) reasoning, with Edge-Finding (EF), with No (N) additional propagation. Each curve shows the number of instances solved in a given amount of CPU time.

The effect of the different satisfiability tests and time-bound adjustment algorithms clearly depends on the set of instances. Considering only the instances solved by all versions of the branch and bound (39 over 40 for the BL set and 353 over 480 for the KSD set), the reduction in the average number of backtracks between N and EG is equal to 97% and 24% on the BL and KSD sets respectively. On the KSD sets, the cost of the more complex time-bound adjustment algorithms is not balanced by the subsequent reduction of search, and the CPU time increases. On the contrary, EG performs much better than N on the BL set.

13.4 Conclusion

We have empirically evaluated several propagation techniques for cumulative resources. These techniques can be used not only for standard scheduling problems; some of them can also be used for preemptive scheduling problems (e.g., partially elastic relaxation as defined in Section 9.2.3 or for fully elastic problems (e.g., fully elastic relaxation as defined in Section 9.1). Propagation proves to be effective on some, but not all problem instances in the cumulative scheduling class. Computational results have shown that, on “highly disjunctive” project scheduling instances, the more complex constraint propagation algorithms induce an overhead that is not balanced by the resulting reduction of search. On the other hand, the most expensive techniques prove to be highly useful for the resolution of less highly disjunctive problems.
Let us remark that the branch and bound procedure does not incorporate all the results obtained by other researchers for the Resource-Constrained Project Scheduling Problem (RCPSP). In particular, we have not used, until now, any “intelligent backtracking” rule such as the cut-set rule of Demeulemeester and Herroelen [83]. This may seem a little “strange” given the excellent results reported in [84], in particular on the KSD instances, even with a limited use of the cut-set rule. It appears that many industrial scheduling problems include several additional features (including, for example, elastic activities) which seem to require the use of other techniques. Yet in the case of the pure RCPSP, it would be interesting to determine how subsequent improvements of the procedure would influence computational results, and hence our conclusions on the usefulness of the various propagation techniques.

Recently, several new lower bounds based on Linear Programming (LP) formulations of a relaxed RCPSP have shown to be very accurate [46, 166]. However, the size of the models used is so large
that, even with complex column generation techniques, hours of CPU time are sometimes required to get a lower bound. Recently, Carlier and Néron [60] have shown that for each resource, an efficient LP-based lower bound can be tabulated, for each fixed value of the resource capacity. Thus, the computation of the bounds is not time consuming! This is, we think, one of the most promising research direction for the next few years.
Cumulative Scheduling Problems
Chapter 14

Min-Sum Scheduling Problems

We illustrate and compare the efficiency of the constraint propagation algorithms described in previous chapters on two well-known scheduling problems. In Sections 14.1 and 14.2 we respectively study the problems of minimizing the weighted number of late jobs on \( m \) parallel identical machines and the total tardiness on 1 machine. In Section 14.3 we consider a general-shop scheduling problem with sequence-dependent setup times and alternative machines where the optimization criteria are both makespan and sum of setup times.

14.1 Minimizing the Weighted Number of Late Jobs

The problem \( P|r_i| \sum w_i U_i \) is very close to the resource constraint of Section 11.1. An instance of the decision-variant of this problem consists of a set of jobs \( \{J_1, \ldots, J_n\} \), a set of \( m \) identical parallel machines, and an integer \( W \). Each job \( J_i \) is described by a release date \( r_i \), a due date \( d_i \), a processing time \( p_i \), and a weight \( w_i \). The problem is to find an assignment of start times to jobs such that:

- less than \( m \) jobs are scheduled at each time point,
- each job starts after its release date,
- the weighted number of jobs that end after their due date is lower than or equal to \( W \).

A job scheduled between its release date and its due date is “on-time”. Conversely, a job that ends after its due date is “late”. Even for the simple unweighted version of the problem \( (1|r_i| \sum U_i) \), few exact approaches have been proposed.

- An efficient heuristic and a branch and bound procedure have been proposed in [79]. It is shown that the problem can be modeled by a Mixed Integer Program (MIP). Unfortunately, instances with more than 10 jobs could not be considered because of the size of the MIP.
- A branch and bound scheme based upon a “master sequence”, i.e., a sequence containing at least an optimal sequence, is proposed in [80]. Lower bounds are obtained by relaxing the release and the due dates according to the Kise, Ibaraki and Mine conditions [129].
- Another branch and bound procedure is presented in [181] where a lower bound is obtained by a Lagrangian relaxation of a MIP formulation.

The last three methods are in the same range of efficiency (95% of instances with 80 jobs can be optimally solved in a reasonable amount of time). Obviously, this problem fits our Constraint-Based Scheduling model. The \( m \) parallel machines are modeled by a resource of capacity \( m \) and each job \( J_i \) is modeled by an activity \( A_i \) that requires one unit of the resource. The initial domain of the start and end variables are set respectively to \([r_i, \ub - p_i]\) and to \([r_i + p_i, \ub]\), \( \ub \) being an upper bound of the completion time of the jobs (e.g., \( \ub \) can be set as the maximum release date plus the sum of all

\[\]
processing times). The domain of the criterion variable \textit{criterion} is set to \([0, W]\). Finally, the cost function is the sum of \(n\) functions \(f_i(\text{end}(A_i))\) that equal \(0\) if \(\text{end}(A_i) \leq d_i\) and \(w_i\) otherwise.

Let us remark that, with this model, \(d_i\) remains arbitrarily large (equal to \(ub\)) as long as it is not decided that \(J_i\) must be on-time.

### 14.1.1 Dominance Relations

Dominance relations allow to reduce the search space to schedules that have a particular structure. The most important dominance relation relies on the idea that it is better to schedule small and heavy jobs with large time windows than large and light jobs with small time windows. We also use two other dominance rules that respectively fix the start times of some jobs and split the problem into distinct subproblems.

**Dominance of Small Jobs with Large Time-Windows**

We rely on the observation that on any solution, if a large job \(J_j\) is on-time and is scheduled inside the time window \([r_i, d_i]\) of a smaller job \(J_i\) that is late, and if \(J_i\) is heavier than \(J_j\), the jobs \(J_i\) and \(J_j\) can be “exchanged”, i.e., \(J_i\) becomes on-time and \(J_j\) becomes late. More formally our dominance rule is based upon the binary relation “\(<\)”.

**Definition 32.** For any pair of jobs \(J_i, J_j, J_i < J_j\) if and only if

\[
\begin{cases}
(p_i < p_j) \lor (p_i = p_j \land i < j) \\
w_i \geq w_j \\
r_i + p_i \leq r_j + p_j \\
d_j - p_j \leq d_i - p_i
\end{cases}
\]

The relation “\(<\)” is transitive and \(\forall J_i, \forall J_j, J_i < J_j \Rightarrow J_i \neq J_j\). Thus, it defines a strict partial order on jobs. Proposition 89 is the theoretical basis of our dominance rule.

**Proposition 89.** There is an optimal schedule such that for any pair of jobs \(\{J_i, J_j\}\), if \(J_i < J_j\) and \(J_j\) is on-time, then \(J_i\) is also on-time, i.e.,

\[
\forall J_i, \forall J_j, \neg[(J_i < J_j) \land (\text{end}(J_j) \leq d_j) \land (\text{end}(J_i) > d_i)]
\]  

(14.1)

**Proof.** Consider an optimal schedule \(Q\) such that the first index \(i\) for which there exists a job \(J_j\) that violates (14.1) is maximum. We have \((J_i < J_j) \land (\text{end}(J_j) \leq d_j) \land (\text{end}(J_i) > d_i)\). We build a new schedule obtained by “exchanging” \(J_i\) and \(J_j\). More precisely, \(J_i\) is scheduled at the maximum of \(r_i\) and of the start time of \(J_j\) in \(Q\). \(J_j\) is scheduled after all other jobs (it then becomes late). It is obvious to verify that the new schedule is still feasible and optimal. Moreover, \(J_i\) is now on-time. Now, suppose that there exists a late job \(J_k\) such that \(J_k < J_i\). We then have \(J_k < J_i < J_j\). Moreover, \(J_k\) was also late on the initial schedule. Consequently, \(k > i\) because of the choice of \(i\). This contradicts our hypothesis on the choice of the initial schedule. \(\square\)

Remark that the constraint in Proposition 89 still holds if \(r_j + p_j\) is replaced by \(\text{end}(J_j)\) and if \(d_j - p_j\) is replaced by \(\text{start}(J_j)\). Arc-consistency is achieved on this new constraint. It allows to prove that some jobs must be late or on-time and it tightens the domains of the start variables.

**Decomposition Rule**

The basic idea of the decomposition is to detect some cases in which the problem can be split into two subproblems. Each of them being solved independently.

**Proposition 90.** Let \(t_1\) be a time point such that for any non-late job (i.e., \(\text{et}_i \leq d_i\)), either \(\min(d_i, d_i) \leq t_1\) or \(t_1 \leq r_i\). Any optimal schedule, is the “sum” of an optimal schedule of \(\{J_i: \text{et}_i \leq d_i \land \min(d_i, d_i) \leq t_1\}\) and of an optimal schedule of \(\{J_i: \text{et}_i \leq d_i \land t_1 \leq r_i\}\).
On-time jobs are either in 
\{J_i : \text{eet}_i \leq d_i \land \min(\bar{d}_i, d_i) \leq t_1\} \text{ or in } \{J_i : \text{eet}_i \leq d_i \land t_1 \leq r_i\} \text{ and they do not compete for the machine.}

We only consider the values of \(t_1\) that are earliest start times (if the problem can be decomposed at time \(t_1\), it is easy to verify that it can also be decomposed at the first \(r_i\) after \(t_1\)). There are \(O(n)\) distinct earliest start times and the decomposition test (at a given time point) obviously runs in linear time. Consequently, the overall decomposition test runs in \(O(n^2)\). Once the problem has been decomposed, the optimum of each subproblem is computed and we simply have to verify that the sum of these optima is lower than or equal to \(W\).

**Straight Scheduling Rule**

We use a simple dominance rule which schedules automatically a set of jobs if they “fit” in a particular interval.

**Proposition 91.** Let \([t_1, t_2]\) be any time interval. Let \(J(t_1, t_2)\) be the jobs, among those that are not late yet (i.e., \(\text{eet}_i \leq d_i\)), that may execute (even partially) in \([t_1, t_2]\) if they are on-time (i.e., \(t_1 < \min(\bar{d}_i, d_i) \land t_2 > r_i\)). Moreover, suppose that there exists a feasible schedule \(Q\) of \(J(t_1, t_2)\) that is idle before \(t_1\) and after \(t_2\) on which all jobs are on-time. Then there exists an optimal overall schedule \(R\) of \(\{J_1, \ldots, J_n\}\) such that between \(t_1\) and \(t_2\) the schedules \(Q\) and \(R\) are identical.

**Proof.** Obvious.  

Consider now any time point \(t_1\) and let \(J(t_1)\) be the set of jobs \(J_i\) that do not have to be late and that can end after \(t_1\) (\(t_1 < \min(d_i, \bar{d}_i))\). We build a schedule of \(J(t_1)\) as follows: Each time a job is completed, the available job with the smallest due date \(\min(\bar{d}_i, d_i)\) is scheduled. Let \(t_2\) be the current time point throughout the construction of the schedule:

1. if a job is completed after its due date then \(t_1\) is not a valid candidate for straight scheduling
2. if \(J(t_2)\) becomes empty then we have built a valid schedule of \(J(t_1, t_2)\) where all jobs are on-time.

Now remark that if \(t_1\) is not in \(\{\min(\bar{d}_1, d_1), \min(\bar{d}_2, d_2), \ldots, \min(\bar{d}_n, d_n)\}\) then \(J(t_1 - 1, t_2) = J(t_1, t_2)\) and a schedule that can fit in \([t_1, t_2]\) can also fit in \([t_1 - 1, t_2]\). Hence, the “straight scheduling rule” is applied for \(t_1 = \min(r_i)\) and for \(t_1 \in \{\min(\bar{d}_1, d_1), \min(\bar{d}_2, d_2), \ldots, \min(\bar{d}_n, d_n)\}\). In the following experiments, this rule is active only if the machine capacity is 1.

### 14.1.2 Branching Scheme

We use the dichotomizing algorithm of Section 7.2.5. The critical part is the resolution of the decision problem. The search tree is built as follows: While there are some jobs that can be late or on-time (i.e., \(\text{eet}_i \leq d_i < \bar{d}_i\)),

1. select a job \(J_i\) such that \(\text{eet}_i \leq d_i < \bar{d}_i\)
2. constrain \(J_i\) to be on-time, i.e., \(\text{end}(J_i) \leq d_i\) (if a backtrack occurs, \(J_i\) must be late)
3. apply dominance rules and propagate constraints
4. check that there exists a feasible schedule of the jobs, i.e., a schedule where all jobs are scheduled in their time-window, (if not, the problem is inconsistent and a backtrack occurs).

When the branch and bound succeeds, it has been decided for each job whether it is on-time or not. On top of that the weighted number of late jobs equals criterion (because arc-B-consistency is enforced on the criterion constraint). Moreover there is a feasible schedule of the jobs (step 4). Let us detail the heuristic used for the job selection and the procedure that checks whether there is a feasible schedule of the jobs that must be on-time.
Job Selection Heuristic

Let $U$ be the set of jobs $J_i$ that can be late or on-time (i.e., $eet_i \leq d_i < \bar{d}_i$). Let $\max_i(w_i/p_i)$ be the maximum value of $w_i/p_i$ among jobs in $U$ and finally, let $S$ be the subset of the jobs $J_j$ in $U$ such that $w_j/p_j > 0.9 * \max_i(w_i/p_i)$. Among jobs in $S$, we select a job whose time window, if it becomes on-time, i.e., $[r_i, d_i]$, is the largest. This heuristic “bets” that it is better to schedule small and heavy jobs with large time windows rather than large and light jobs with tight time windows.

Feasibility Check

The aim of this step is to determine if there is a feasible schedule of the jobs that meets all time-windows. Even on a single machine, this problem is NP-hard in the strong sense. A large amount of work has been carried on this problem because it serves as the basis for the resolution of several disjunctive scheduling problems. The branch and bound algorithm of Carlier [54] has shown to be extremely efficient for this problem. Very large instances can be solved in a few amount of time. Hence, it is used as soon as the number of machines equals 1. Unfortunately, there is no such efficient algorithm in the cumulative case. Hence we use a procedure similar to the one described in Section 13.1 for the Resource-Constrained Project Scheduling Problem (in our case, there is no precedence constraint and resource requirements are unitary). The Left-Shift / Right-Shift propagation technique is used at this point (cf., Section 9.3.6).

14.1.3 Computational Results

In this section we compare the efficiency of the constraint propagation algorithms described in previous chapters on the problem of minimizing the weighted number of late jobs. Several instances of $P|r_j|\sum w_jU_j$ have been generated following the generation scheme of [24, 17]. We pay attention to four important characteristics:

- The distribution of the processing times.
- The distribution of the weights.
- The overall “load” of the machines; where the load is the ratio between the sum of the processing times of the jobs and $m * (\max_i d_i - \min_i r_i)$.
- The margin $m_i = d_i - r_i - p_i$ of each job.

Our generation scheme is based on 6 parameters: the number of jobs $n$, the number of machines $m$, and the four statistical laws followed by the processing times, the weights, the release dates, and the margins (given $r_i$, $p_i$ and $m_i$, the due date can be immediately computed $d_i = m_i + r_i + p_i$).

- Processing times are generated from the uniform distribution over $[p_{\min}, p_{\max}]$.
- Weights are generated from the uniform distribution $[1, w_{\max}]$.
- Release dates are generated from the normal distribution $(0, \sigma)$.
- Margins are generated from the uniform distribution $[0, m_{\max}]$.

Given these parameters and relying on the fact that most of the release dates are in $[-2\sigma, 2\sigma]$, the load is approximately equal to:

$$\text{load} = n \frac{p_{\min} + p_{\max}}{2m(4\sigma + p_{\max} + m_{\max})}$$

Given $n, p_{\min}, p_{\max}, m_{\max}$ and load, this allows us to determine a correct value of $\sigma$. One instance has been generated for each of the combinations of the parameters $(n, m, (p_{\min}, p_{\max}), m_{\max}, \text{load}, w_{\max})$. See Table 14.1. Tables 14.2, 14.3, and 14.4 report the results obtained for the three different values of $m$. Each line summarizes the results obtained on a set of 90 instances of the same size $n$. The
column “% solved” provides the ratio of instances that have been solved within 600 seconds of CPU time on a PC HP Vectra 350 MHz running Windows 95. The columns “Avg. CPU” and “Avg. BCK” report respectively the average CPU time in seconds and the average number of backtracks required to solve the instances. The column “Max CPU” reports the maximum CPU time. Instances that could not be solved within the time limit are not taken into account in these computations.

The algorithm behaves well since, on the average, 79.3 % of the 50 jobs instances can be solved in less than 10 minutes of CPU time. However, it appears that instances with parallel machines are much more difficult to solve than those with a single machine. This is due, we think, to the fact that our branching scheme is very efficient when we can use the algorithm of [54] for the feasibility check. A careful examination of the computational results shows that for \( m > 1 \) more than 90 % of the CPU time is spent in the feasibility check. Excellent results have been reported recently in [25] for the special case where \( m = 1 \) and \( \forall i, w_i = 1 \). Lower bounds based on Lagrangian relaxation and on relaxations of the problem to polynomially solvable cases are proposed. New elimination rules together with strong dominance relations are also used to reduce the search space. A branch and bound procedure exploiting all these techniques solves to optimality problems with up to 200 jobs.

### 14.2 Minimizing Total Tardiness

Consider the scheduling situation where \( n \) jobs \( J_1, \ldots, J_n \) have to be processed by a single machine and where the objective is to minimize total tardiness. Associated with each job \( J_i \), are a processing time \( p_i \), a due date \( d_i \), and a release date \( r_i \). A job cannot start before its release date, preemption
is not allowed, and only one job at a time can be scheduled on the machine. The tardiness of a job $J_i$ is defined as $T_i = \max(0, C_i - d_i)$, where $C_i$ is the completion time of $J_i$. The problem is to find a feasible schedule with minimum total tardiness $\sum T_i$. The problem, denoted as $1\mid r_i \mid \sum T_i$, is known to be NP-hard in the strong sense.

A lot of research has been carried on the problem with equal release dates $1\mid \sum T_i$. Powerful dominance rules have been introduced by Emmons (see Section 11.2.2). Lawler [143] has proposed a dynamic programming algorithm that solves the problem in pseudo-polynomial time.

Most of the exact methods for solving $1\mid \sum T_i$ strongly rely on Emmons’ dominance rules. Potts and Van Wassenhove [186], Chang et al. [73] and Szwarc et al. [208], have developed Branch-and-Bound methods using the Emmons rules coupled with the decomposition rule of Lawler [143] together with some other elimination rules. The best results have been obtained by Szwarc, Della Croce and Grosso [208] with a Branch-and-Bound method that efficiently handles instances with up to 500 jobs!

There are less results on the problem with arbitrary release dates. Chu and Portmann [74] have introduced a sufficient condition for local optimality which allows to build a dominant subset of schedules. Chu [75] has also proposed a Branch-and-Bound method using some efficient dominance rules. This method handles instances with up to 30 jobs for the hardest instances and with up to 230 jobs for the easiest ones.

In Section 14.2.1, we describe the overall branching scheme. In Sections 14.2.3 and 14.2.2, we introduce some dominance properties and we finally report our experimental results in Section 14.2.5. We will see that our procedure handles instances as large as 500 jobs although some 60 jobs instances remain open.

### 14.2.1 Overall Scheme

All propagation rules described in Section 11.2 are used. On top of this, we rely on the edge-finding branching scheme. Rather than searching for the starting times of jobs, we look for a sequence of jobs. This sequence is built both from the beginning and from the end of the schedule. Throughout the search tree, we dynamically maintain several sets of jobs that represent the current state of the schedule (see Figure 14.1).

- $P$ is the sequence of the jobs scheduled at the beginning,
- $Q$ is the sequence of the jobs scheduled at the end,
- $NS$ is the set of unscheduled jobs that have to be sequenced between $P$ and $Q$,
- $PF \subseteq NS$ (Possible First) is the set of jobs which can be scheduled immediately after $P$,
- and $PL \subseteq NS$ (Possible Last) is the set of jobs which can be scheduled immediately before $Q$.

At each node of the search tree, a job $J_i$ is chosen among those in $PF$ and it is scheduled immediately after $P$. Upon backtracking, this job is removed from $PF$. The heuristic used to select $J_i$ comes from [74, 75]: Among jobs of $PF$ with minimal release date, select the job that minimizes the function $\max(r_i + p_i, d_i)$. Of course, if $NS$ is empty then a solution has been found and we can iterate to the next decision problem. If $NS \neq \emptyset$ while $PF$ or $PL$ is empty then a backtrack occurs. Several

propagation rules relying on jobs time-windows, are used to update and adjust these sets. These rules, known as edge-finding (see Chapter 8) are also able to adjust the time-windows according to the machine constraint.

Due to our branching scheme, jobs are sequenced from left to right so it may happen that at some node of the search tree, all jobs of NS have the same release date (the completion time of the last job in P). In such a case, to improve the behavior of the Branch-and-Bound method, we apply the dynamic programming algorithm of Lawler [143] to optimally complete the schedule.

\[ \text{Figure 14.1: A Node of the Search Tree.} \]

### 14.2.2 Dominance on Equal Length Jobs

We prove that, considering two jobs which have the same processing time, the first Emmons Rule (Section 11.2.2) is valid. Note that, contrary to the Generalized Emmons Rules, this dominance property is valid even in the non-preemptive case.

**Proposition 92.** Let \( J_i \) and \( J_k \) be two jobs such that \( p_i = p_k \). If \( r_i \leq r_k \) and \( d_i \leq \max(r_k + p_k, d_k) \), then there exists an optimal schedule in which \( J_i \) precedes \( J_k \).

**Proof.** Consider a schedule \( S \) in which job \( J_i \) and job \( J_k \) satisfy the assumptions and in which job \( J_k \) is completed before job \( J_i \). Let us exchange \( J_i \) and \( J_k \) in \( S \). Note that the exchange is valid since \( r_i \) is lower than or equal to the earliest start time of \( J_k \). We have \( p_i = p_k \), then the completion time of the other jobs do not change. This exchange does not increase total tardiness (see Section 11.2.2). \( \square \)

### 14.2.3 Removing Dominated Sequences

Several dominance properties have been introduced in [74, 75]. These rules focus on the jobs in NS plus the last job of \( P \). They determine that some precedence constraints can be added. Such constraints allow us to adjust release dates and to filter PF. All these rules are used in our Branch-and-Bound procedure. On top of this, we also consider dominance properties that take into account the complete sequence \( P \). Informally speaking, our most basic rule states that if the current sequence \( P \) can be “improved”, then it is dominated and we can backtrack.

In the following, let \( C_{\text{max}}(P) \) and \( T(P) \) denote the completion time and the total tardiness associated with the current sequence \( P \). Now consider a permutation \( P' \) of \( P \) of and let us examine under which condition \( P' \) is “as good as” than \( P \).

- If \( C_{\text{max}}(P') \leq C_{\text{max}}(P) \) and \( T(P') \leq T(P) \), then we can replace \( P \) by \( P' \) in any feasible schedule so \( P' \) is at least as good as \( P \).

- If \( C_{\text{max}}(P') > C_{\text{max}}(P) \), then if we replace \( P \) by \( P' \) in a feasible schedule, all jobs in \( \text{NS} \cup Q \) have to be shifted of at most \( C_{\text{max}}(P') - C_{\text{max}}(P) \) time units. So, the additional cost for jobs in \( \text{NS} \cup Q \) is at most \( (|\text{NS}| + |Q|)(C_{\text{max}}(P') - C_{\text{max}}(P)) \). Hence, \( P' \) is at least as good as \( P \) if

\[
T(P') + (|\text{NS}| + |Q|)(C_{\text{max}}(P') - C_{\text{max}}(P)) \leq T(P).
\]

\( P' \) is better than \( P \) if \( P' \) is at least as good as \( P \) and if either (1) \( P \) is not at least as good as \( P' \) (2) or if \( P' \) is lexicographically smaller than \( P \). When \( P' \) is better than \( P \), the current sequence is dominated and we can backtrack. To compare two sequences, we just have to build the schedules associated with them and this can be done in linear time.
Enumeration of the $k$ Last Jobs

We can enumerate all permutations $P'$ of $P$ and test if it is better than $P$. Since the number of alternative sequences is exponential, we only consider the permutations $P'$ that are identical to $P$ except for the $k$ last jobs (where $k$ is an arbitrary value). When $k$ is large, we have a great reduction of the search space but this takes a lot of time. Experimentally, $k = 6$ seems to be a good trade-off between the reduction of the search tree and the time spent in the enumeration.

Removing Possible Firsts

We propose a simple technique to detect that a job $J_i \in PF$ cannot be actually scheduled just after $P$ and thus can be removed from $PF$. We note $P \setminus J_i$ the sequence where $J_i$ is scheduled immediately after $P$. If there is a permutation $\pi$ of $P \setminus J_i$ that is “better” than $P \setminus J_i$ then scheduling $J_i$ first after $P$ leads to a dominated schedule and thus we can remove $J_i$ from $PF$. This time we only enumerate the permutations $\pi$ that are obtained from $P \setminus J_i$ either by inserting $J_i$ somewhere inside $P$ or by exchanging $J_i$ with another job of $P \setminus J_i$. Since there are $O(n)$ such permutations and since comparing two sequences can be done in linear time, the algorithm runs in $O(n^2)$ for a given job $J_i$.

Adjusting Deadlines

Consider a job $J_i \in NS$ and assume that the current node of the search tree can be extended to a feasible optimal schedule where $J_i$ is completed at some time point $C_i$. Let $P(\lambda \setminus J_i | |\mu|Q)$ be the sequence of the jobs in the feasible optimal schedule and let us modify this sequence by removing $J_i$ and inserting it somewhere in $P$. The new sequence is $P'(|J_i|P''|\lambda|\mu|Q)$, where $P'\setminus J_i \setminus P''$ is the sequence derived from $P$ after the insertion of $J_i$.

In the following, we assume that $r_i \leq C_{\max}(P')$. Under this hypothesis, it is easy to see that $C_{\max}(P'|J_i|P'')|\lambda| \leq C_{\max}(P)|\lambda|, J_i)$ and thus the tardiness of the jobs in $\mu|Q$ has not been increased. On top of that, the jobs in $\lambda$ have been shifted of at most $C_{\max}(P'|J_i|P'') - C_{\max}(P)$ time units. Thus, the total tardiness of the jobs in $\lambda$ has been increased of at most $|\lambda|(C_{\max}(P'|J_i|P'') - C_{\max}(P)) \leq (|NS| - 1)(C_{\max}(P'|J_i|P'') - C_{\max}(P))$. Finally, the total tardiness of the jobs in $P \cup \{ J_i \}$ has been increased of $T(P'|J_i|P'') - T(P) + \max(0, C_i - d_i)$. Consequently, the total tardiness has been increased of at most

$$(|NS| - 1)(C_{\max}(P'|J_i|P'') - C_{\max}(P)) + T(P'|J_i|P'') - T(P) - \max(0, C_i - d_i).$$

Since the initial schedule is optimal, the above expression is positive and thus,

$$C_i < d_i + (|NS| - 1)(C_{\max}(P'|J_i|P'') - C_{\max}(P)) + T(P'|J_i|P'') - T(P).$$

In other words, the deadline $d_i$ of $J_i$ can be adjusted to

$$\min(d_i, d_i - 1 + (|NS| - 1)(C_{\max}(P'|J_i|P'') - C_{\max}(P)) + T(P'|J_i|P'') - T(P)).$$

Since there are $O(n)$ sequences $P'|J_i|P''$ (with $r_i \leq C_{\max}(P')$) that can be derived from $P$ and since the completion time and the total tardiness of a sequence can be computed in linear time, all adjustments of related to $J_i$ can be computed in $O(n^2)$.

14.2.4 Intelligent Backtracking

Intelligent Backtracking techniques “record”, throughout the search tree, some situations that do not lead to a feasible solution. Each time such a situation is encountered again then a backtrack is immediately triggered.

In practice, when a backtrack occurs, the set of “scheduled” jobs, i.e., those in $P$, the tardiness associated to the sequence ($T(P)$) and and its completion time ($C_{\max}(P)$) are stored. Using a hash table for storing the set of schedule jobs, the total memory requirement is kept relatively low. If latter in the search tree, we are in a situation where a sequence $P'$ of the same jobs as in $P$ jobs has been built and if $T(P') \geq T(P)$ and $C_{\max}(P') \geq C_{\max}(P)$ then the current node of the search tree cannot lead to an optimal solution (otherwise, $P$ could also be extended to an optimal sequence).
14.2.5 Experimental Results

All techniques presented below have been incorporated into a Branch-and-Bound method implemented on top of ILOG Solver and ILOG Scheduler. All experimental results have been computed on a PC Dell Latitude 650 MHz running Windows 98.

The instances have been generated with the scheme of Chu [75]. Each instance is generated randomly from three uniform distributions of $r_i$, $p_i$ and $d_i$. The distribution of $p_i$ is always between 1 and 10. The distributions of $r_i$ and $d_i$ depend on 2 parameters: $\alpha$ and $\beta$. For each job $J_i$, $r_i$ is generated from the distribution $[0, \alpha \sum p_i]$ and $d_i - (r_i + p_i)$ is generated from the distribution $[0, \beta \sum p_i]$. Four values for $\alpha$ and three values for $\beta$ were combined to produce 12 instances sets, each containing 10 instances of $n$ jobs with $n \in \{10, 20, 30, 40, 50, \ldots, 500\}$ jobs.

</tbody>
</table>

Table 14.5: Comparison Between $lb_{Chu}$ and $lb_2$. $n = 20$ Jobs, $\alpha = 0.5$, $\beta = 0.5$, no Dominance Property, no Intelligent Backtracking.

In Table 14.5, Chu’s lower bound is compared with the new lower bound $lb_2$ (see Section 11.2.1). Most times, $lb_1 = lb_{Chu}$ so, $lb_1$ has been skipped from the tables to simplify the presentation. To have a fair comparison of the bounds, the Branch-and-Bound procedure has been run without dominance property nor Intelligent Backtracking on instances with 20 jobs that are known to be hard ($\alpha = 0.5$, $\beta = 0.5$) [75]. Each line corresponds to a single instance and we report the optimal tardiness (Opt.), the value of the lower bound computed at the root of search tree ($lb_{Chu}$, $lb_2$), the relative gap (Gap) between the optimum and the two lower bounds, the number of backtracks (Bck.) and the amount of CPU time in seconds required to solve the instance. A ’***’ in the table indicates that the search was interrupted after 1800 seconds. On the average, $lb_{Chu}$ is at 81% of the optimum value while our lower bound is much closer (6%). The average number of backtracks over the instances solved by both methods has been divided by almost 12 and the CPU time by 37.

In Table 14.6, we show the efficiency of dominance properties, propagation rules and intelligent backtracking technique presented above. For that, the Branch-and-Bound procedure has been run with $lb_3$ on instances with 30 jobs with various combinations of $\alpha$ and $\beta$. On each line of Table 14.6, the average results obtained over the 10 generated instances are reported. In columns 3 and 4 (“Chu”), we report the results obtained when the dominance properties of Chu are used [74, 75]. We then add (columns 5 and 6) the dominance and propagation rules presented in Section 14.2.2 (EQual Processing, EQP), Section 14.2.3 (Remove Dominated Sequences, RDS), and Section 14.2.3 (optimization on the 6 last jobs). Intelligent Backtracking (IB) is then added and results are reported in columns 7 and 8. All “ingredients” are useful to reduce the search space.

The results obtained with the version of the algorithm that incorporates all ingredients are presented in Table 14.7. For each combination of parameters and for each value of $n$, we provide the average number of fails and the average computation time in seconds. A time limit of 3600 seconds has been fixed. All instances are solved within the time limit for up to 50 jobs. For $n = 60$, and for ($\alpha = 0.5$, $\beta = 0.5$), most of the instances cannot be solved. As noticed earlier by Chu [75], instances generated according to this particular combination seem to be “hard” to solve in practice.

</tbody>
</table>

From this table, we can remark that the “hardness” increases very quickly with \( n \), especially for \((\alpha = 0.5, \beta = 0.5)\). For each combination of parameters, we report the largest size of instance (column “Largest”) for which 80% of instances are solved within one hour of CPU time. In practice most of the instances are solved within 30 seconds and our results compare well to those of [75]. For instance, the average number of fails for the combination \((\alpha = 0.5, \beta = 0.5)\) was greater than 36000 in [75], whereas this number is now lower than 300.

### 14.3 Minimizing Makespan and Sum of Transition Times

In this section we consider a General-Shop Problem with sequence-dependent setup times and alternative machines. The optimization criteria are both makespan and sum of setup times. The solution method and the computational study presented here are mostly taken from [103]. The solution method is based on a two phase algorithm where during the first phase we try to find a solution having as good a makespan as possible, and in the second phase the attention is turned to improving the sum of setup times while at least maintaining the quality of the makespan found in the first phase. It is shown that the constraint propagation as described in Section 11.3 considerably improves the performance of the approach.

#### 14.3.1 Problem Definition

We are given a set of \( n \) jobs \( \{J_1, \ldots, J_n\} \) and a set of \( m \) machines \( \{M_1, \ldots, M_m\} \). Each job \( J_i \) has to be processed for \( p_i \) time units on a machine \( M_u \) that can be chosen from a given subset of the \( m \) machines. Between jobs, sequence-dependent setup times exist that also depend on which machine is used to process the jobs. Jobs may furthermore be linked by precedence relations \( J_i \rightarrow J_j \), denoting that job \( J_j \) cannot start before the end of job \( J_i \).

This problem obviously fits our Constraint-Based Scheduling model (see Section 7.2). Jobs are simply modeled by activities (to stay in the terminology of the problem we will continue to talk about jobs instead of activities in this section) and we have alternative machines for the jobs. The setup time between jobs \( J_i \) and \( J_j \) on machine \( M_u \) is represented by \( \text{setup}(J_i, J_j, M_u) \), the setup time before \( J_i \) by \( \text{setup}(-, J_i, M_u) \), and the teardown time after \( J_i \) by \( \text{setup}(J_i, -, M_u) \) (see Section 7.2.4 for details).

The objective is first to find a schedule with minimal makespan, after which the sum of setup times is to be minimized. The constraint propagation on the sum of setup times that is used is
Table 14.7: Results Obtained with up to 60 Jobs.
14.3.2 Problem Solving

The problem is solved in two phases. During the first phase a good but not necessarily optimal solution with respect to makespan is searched for. With $C^*$ the best makespan found in this phase, in the second phase a constraint is added imposing that any further solution will have a makespan smaller or equal to $C^*$. Constraint-based local improvement methods are then used to minimize the sum of setup times.

First Phase Heuristic

We use a time-limited, incomplete branch and bound method to try to find a solution that minimizes the makespan. At each node of the search tree we administer for each machine which job has been scheduled last. The set $B$ contains all these jobs. By analyzing the precedence graph, we choose a job $J_i$ among the set of jobs that are still unscheduled and can be next to one of the jobs in $B$. We branch on the relative position of $J_i$ forcing $J_i$ to be either next or successor but not next of one job in $B$. Among all jobs that can be chosen we select the one having the smallest earliest start time and, in case of ties, the one having the smallest latest end time. In the branch of the tree imposing $J_i$ next to one job in $B$, we also need to choose the machine assignment for $J_i$. If several machine assignments are feasible we heuristically choose the machine assignment that allows to schedule the job as early as possible, and in case of ties, the one which generates the smallest setup time.

Setup Optimization

In the setup optimization phase, given a solution having a makespan equal to $C^*$, we search for solutions that have a makespan less or equal to $C^*$ and that minimize the sum of setup times. For this the following local improvement procedure based on time windows is used. A time window $[TW^L_k, TW^U_k]$ defines a subproblem $P_{TW^k}$ in the following way. On every machine, all jobs on the left of the window have their start times and machine assignments fixed; all jobs on the right of the time window have their machine assignment and their sequence on the machines fixed (the variable next is fixed); all jobs within the current window are completely free. On each subproblem a time-limited branch and bound search is performed to try to find the optimal solution for $P_{TW^k}$.

Two different methods have been used to select the current window. The first one is a simple “gliding window” method. The second one (LB-based Window Selection) relies on the computation of a lower bound of the sum of setup times to select the most promising window.

Gliding Window

Given a fixed size of the window $W_{size}$ and a window offset $W_d$, the Gliding Window method starts the setup optimization at $P_{TW^0}$ defined by window $[0, W_{size}]$, optimizes the problem, and then moves the window by $W_d$ to the right, i.e.,

$$P_{TW^{k+1}} := [TW^L_k + W_d, TW^U_k + W_d]$$

This is repeated until the end of the schedule is reached. At the end of each loop, the window size and offset can eventually be modified and another loop can be performed.

LB-based Window Selection

This method is based on the idea to first work on the parts of the schedule where we can hope to obtain the highest improvement. For a given subproblem $P_{TW^k}$, defined by window $[TW^L_k, TW^U_k]$ we can calculate the expected improvement on the objective function $E_{TW^k}$ as the difference between the current sum of setup times in that window, and the lower bound calculated in that window. After subproblem $P_{TW^k}$ is defined, variable $Z$ identifying the sum of setup times contains the information of the lower bound calculated by the constraint propagation. Crucial components of the constraint propagation are the route optimization constraint and the precedence graph constraint of
Section 11.3. So, if $s^*$ is the total setup value of the current best solution found, $E_{TW^k}$ is equal to $s^* - lb(Z)$. In the LB-based Window Selection, first $E_{TW^k}$ is calculated for each subproblem $P_{TW^k}$ as defined in the Gliding Window procedure. Then the subproblems are sorted in descending order of $E_{TW^k}$. All subproblems that may lead to an improvement of the objective function are labeled as improvable. We run the branch and bound algorithm on the first ranked subproblem that can lead to an improvement, and change the label of the window. If a better solution is found, the current solution is updated, and the values $E_{TW^k}$ of all windows on the right of the modified one are recalculated since they may have been changed by the new solution. Also, the labels of the windows on the right are updated. The windows are then re-sorted and the procedure is repeated until no window exists that is labeled to be improvable.

### 14.3.3 Computational Results

The computational results in [103] that we present here show that the constraint propagation as described in Section 11.3 improves performance of the approach both in terms of computation time and quality of solutions. Other constraint propagation used for this problems includes the basic propagation on temporal relations and alternative machines as described in Section 7.2, the disjunctive constraint propagation of Section 8.1.2, and Edge-Finding as described in Section 8.1.3. It is shown that the large neighborhood defined by a time window containing between 30 and 60 jobs can be very efficiently explored thanks to this constraint propagation.

#### Instance generation

Following the computational studies in [51], experiments are run on Open-Shop, General-Shop, and Job-Shop Problems. The instances of [51] are used to test the approach on problems with setup times but without machine alternatives. These instances were duplicated and triplicated in [103] to generate scheduling problems with setup times and alternative machines. In order to generate an instance with the alternative choice of $k$ machines, for each job and each machine in the original instance, $k$ jobs and $k$ machines are created. If in the original instance job $J_i$ requires machine $M_{j_i}$ in the $k$–multiplied instance each one of the $k$ identical jobs $J_{ih}$ requires one out of the $k$ identical machines $M_{jh}$. The temporal constraints among jobs are also duplicated, so that if a temporal constraint $J_i \rightarrow J_j$ exists in the original instance, the set of temporal constraints $J_{ih} \rightarrow J_{jh}$ exist in the new instance. For all instances without alternative machines the results of the approach described here can be compared to the results published in [51]. Nevertheless, a real comparison cannot be done since in [51] the objective is the minimization of the makespan, while here the aim is to minimize the sum of setup times in a problem constrained by a maximal makespan.

The Open-Shop instances with no alternative machines contain 8 machines and 8 jobs (16 machine and 16 jobs for the 2-alternative instances etc.). The General-Shop instances with no alternative machines also contain 8 machines and 8 jobs, and derive from the Open-Shop instances with the addition of temporal constraints (see [51]). The Job-Shop instances with no alternative machines contain 5 machines and 20 jobs.

#### Results

Tables 14.8, …, 14.16 report results on Open-Shop, General-Shop, and Job-Shop instances. Tables 14.8, 14.9, and 14.10 report results for the instances in [51]. The following tables report results for the duplicated and triplicated instances generated as described above. For each instance the results obtained by the first solution phase and the setup optimization phase are reported in terms of sum of setup times ($\sum tt$) and makespan ($C^*$). We also report in column B&T the results published in [51] in terms of makespan for all the instances with no alternative machine. The numbers in the tables that are in boldface indicate the best value found for the instance at hand. All tests were run on a Pentium II 300 MHz. The results published in [51] were obtained on a Sun 4/20 workstation, with a time limit of 5 hours for Open-Shop and General-Shop instances, and a time limit of 2 hours for Job-Shop instances.
Column “FirstSol” reports results in terms of makespan and sum of setup times of the best solutions obtained by the first solution phase. The time limit given was 60 seconds, and limited discrepancy search was used (see [116] and Section 12.3.4). The solution obtained after this first phase turns out to be a good solution with respect to makespan minimization. In half of the instances considered, the makespan found in the first solution phase improves the best known makespan published in [51].

As explained, the results of the first solution phase were used as a starting point for the setup optimization. In the setup optimization phase we fixed an initial window size of 30 jobs (i.e., each subproblem has 30 completely free jobs), and we used a time limit of 5 seconds for the branch and bound algorithm to minimize the sum of setup times in each subproblem. In order to compare the results obtained with and without the constraint propagation described in Section 11.3, we used the same, very simple, branching strategy: we choose the variable next with the smallest domain and we branch on its possible values starting from the one generating the smallest setup time. Given an initial window size, the setup optimization methods (columns “GW”, “GW+”, “LBWS”) are called until a local minimum is reached, then the window size is increased 20% (e.g., from 30 free jobs to 36 free jobs), and the procedures are repeated until a global time limit is reached.

Table 14.10: Job-Shop instances from [51]

Column “GW” and column “GW+” report the results obtained by the Gliding Window method described in Section 14.3.2. The algorithm used for column “GW” does not use the constraint propagation of Section 11.3, while the algorithm used for column “GW+” does. Column “LBWS” reports the results obtained by the LB-based Window Selection method (also described in Section 14.3.2). For the Open-Shop and General-Shop instances of Tables 14.8 and 14.9 (containing 64 jobs each), the global time limit used is 30 seconds. For the Job-Shop instances of Table 14.10 (containing 100 jobs each), and for the Open-Shop and General-Shop instances of Tables 14.11 and 14.12 (containing 128 jobs each), the global time limit used is 60 seconds. For the Job-Shop instances of Table 14.13 (containing 200 jobs each), and for the Open-Shop and General-Shop instances of Tables 14.14 and 14.15 (containing 192 jobs each), the global time limit used was 120 seconds. For the Job-Shop instances of Table 14.16 (containing 300 jobs each), the global time limit used is 240 seconds.

When the propagation algorithms of Section 11.3 are used (“GW+”), the solutions obtained

**Table 14.16: Job-Shop instances with three alternative machines**
consistently have at least the quality obtained when this propagation is not used ("GW"), and very often the quality is significantly better. The improvement in the solution quality is particularly important for problems with two and three alternative machines. Problems with no alternative machines are easier and even without the extra propagation, in each window the local optimal solution can often be found. However, even in these cases, when the extra constraint propagation is used the subproblems are solved up to optimality in a shorter time.

A comparison between the LBWS and GW+ shows that the best solutions are equally distributed between the two. Thus neither of the two methods clearly dominates the other. What one could remark is that if the scheduling problem is small enough to allow one or several complete gliding window loops, the LB-based method may lose some interest: if all windows are considered, the order in which they are solved may not be too important. On the other hand, for larger problems a complete gliding window loop may not be possible within the CPU time available. In such cases, a fast evaluation of the most promising area for improvement may play an important role. For more details on the performance improvements in these tests due to using the constraint propagation of Section 11.3, we refer to [103].

Although the aim of the methods proposed is to study the problem including alternative machines, some additional tests were run on small instances with no alternative machines taken from [51]. Open-Shop and General-Shop instances contain 4 machines and 4 jobs, while Job-Shop instances contain 5 machines and 10 jobs. For each instance two results are reported in Table 14.17. Column \(C^*\) before \(\sum tt\) reports the results obtained by first optimizing the makespan, and then given this makespan optimizing the sum of setup times. Column \(\sum tt\) before \(C^*\) reports the results obtained by first optimizing the sum of setup times, and then given this sum of setup times optimizing the makespan.

Table 14.17: Results on “small” instances

In all cases where a computation time is reported, the optimal solution could be proven for both criteria. For example, the optimal makespan of TAIBS01 is 306, and given such a makespan the optimal sum of setup times is 380; on the other hand, the optimal sum of setup times of TAIBS01 is 320, and given this sum of setup times the optimal makespan is 384. Where the time is not reported, optimality could not be proven within 30 minutes.

Two conclusions can be drawn from these results. First, the minimization of only one objective may generate poor quality solutions for the other objective. This indicates the usefulness of considering multi-criteria objectives in future research. Second, it appears that for small problems it is possible to fix any limit for one objective and find the optimal solution for the other objective.
Therefore the method described here might be usable to optimize any combination of makespan and sum of setup times and find a set of Pareto-optimal solutions.
Chapter 15

Conclusion

The various examples provided in Chapters 6, 7, and 8 have shown how a general Constraint-Based Scheduling model and the associated constraint propagation algorithms can be used to enable the resolution of complex scheduling problems.

On disjunctive scheduling problems (e.g., Job-Shop, Open-Shop), the CP approach is competitive with classical OR techniques. Indeed, the most crucial “ingredients” from the successful OR algorithms (e.g., Edge-Finding) have been adapted to the CP framework and are now routinely used as part of industrial constraint-based applications. The CP framework also enables the resolution of NP-hard preemptive problems (e.g., Preemptive Job-Shop). We are not aware of any other practical attempt to solve such problems. In this latter case, the generalization of non-preemptive techniques to a less constrained situation has enabled the implementation of the first efficient problem-solving algorithm for Preemptive Job-Shop Scheduling.

On cumulative problems, computational studies have shown that good results can be obtained for most problem instances. Yet it appears that dedicated OR algorithms are still more efficient than CP on some problem instances (for example, on “highly disjunctive” instances of Section 13.3). Understanding the “structure” of the instances that resist to current CP tools and designing new techniques (e.g., new lower-bounding and new constraint propagation algorithms) to handle these instances constitute a major research direction for the next few years.

Chapters 5 and 8 focused on the importance of objective functions and showed how they can be integrated in a constraint-based framework. Very good results have been obtained on some particular problems (e.g., total weighted number of late jobs, sum of transition times) but of course many other objective functions (e.g., total tardiness, total flow-time) still have to be studied. Designers of scheduling applications often have to define their own criteria. A research challenge is to design generic lower-bounding techniques and constraint propagation algorithms that could work for many criteria.

Similarly, designers of scheduling applications often have to define and add their own constraints to the basic Constraint-Based Scheduling model. The strength of the CP framework in this situation is that the results of propagating the additional constraints are automatically combined with the results of the deductive rules and algorithms presented in this manuscript, thereby creating a “snowball” effect: As long as one constraint can contribute to the reduction of the domain of one variable, the constraint propagation process continues and the domains are reduced. In this sense, additional constraints do not prevent the use of predefined constraint propagation algorithms (available in libraries) and contribute to making these algorithms more effective. In practice, three issues must however be taken into account:

- For complex additional constraints, the design and the implementation of efficient constraint propagation algorithms is not an easy task. In practice, if more than one scheduling application includes a given type of constraint, it might be worth developing once an efficient version of the corresponding constraint propagation algorithms. Examples of scheduling constraints that do not appear in the model of Chapter 1, but appear in libraries, include energy resource constraints, stating that the energy available from a resource over intervals of a given length is
limited (e.g., an employee works no more than 40 hours a week); *energy temporal constraints*, stating that at least some amount of energy must be spent by a given resource on a given activity before or after the beginning or the end of another activity; *state resource constraints*, enabling two activities to overlap only if they require a given resource in the same state (e.g., two products can be cooked in the same oven at the same time only if they require the same oven temperature); *reservoir constraints*, stating that the level of a given reservoir, filled and unfilled by given activities, must remain over a given limit; etc.

- Constraint propagation, especially when complex algorithms are used, takes time. In general, the more complex constraint propagation algorithms prune more values from the domains of the variables but take more time to execute. When search is performed, this results in a smaller search tree but with more time spent at each node. The best combination of constraint propagation algorithms depends on the application and, for the same application, can vary from a problem instance to another. When several constraint propagation algorithms exist for the same constraint, the designer of the application must therefore decide which combination of algorithms is going to be used. This can usually be done by intuition (if the designer knows which constraints will be the most difficult to satisfy) and experimentation (assuming a representative set of problem instances is available). Theoretical “domination” results (e.g., the results presented in Chapter 4) and experimental results from the literature can also be useful. Although necessarily incomplete, the theoretical and experimental comparisons provided in this manuscript hopefully provide a clear overview of the state of the art in the field and clarify a rather complex research situation.

- In some cases, it can be worth developing a global propagation algorithm for a collection of constraints. This is typically what is done in Chapter 5, where the resource constraint and the constraint defining the objective function are mixed to make constraint propagation more effective. Another interesting case is the combination of temporal and resource constraints (cf., for example, [179, 204, 138]). As previously, if more than one scheduling application includes a given combination of constraints, it might be worth developing an efficient constraint propagation algorithm for this combination.

This manuscript dealt with combining OR and AI techniques in a way that preserves the best of both, i.e., the efficiency provided by OR and the generality of approach offered by AI. Some readers might wonder why little has been said about various forms of local search, such as simulated annealing, tabu search, genetic algorithms, etc., which provide excellent results when one can define a compact representation of the solution space that is consistent with the objective function. In real life, problems often incorporate side constraints that tend to disable the local search approach. This led several researchers to integrate CP and local search techniques (cf., for example, [68, 71] in the scheduling domain and [183, 200, 128, 70, 71] in the vehicle routing domain for which this approach has been the most successful).

Similarly, little has been said about Linear Programming (LP) and Mixed Integer Programming (MIP). As a matter of fact, several constraint propagation algorithms in the manuscript do solve linear programs, but usually these programs have enough structure to allow the design of specific algorithms with low complexity. Obviously, this does not mean that LP is useless in the context of Constraint-Based Scheduling.

- For cumulative problems, the complexity of specific constraint propagation algorithms tends to raise (e.g., to $O(n^3)$), which suggests that lower-bounding and constraint propagation algorithms based on LP might be competitive. However, most of the existing lower bounds based on LP are still very time consuming and cannot be computed at each node of a search tree.

- LP can also be a strong “ingredient” when the objective function is a sum or a weighted sum of scheduling variables like the end times of activities. A key research issue here is the design of techniques combining the power of efficient constraint propagation algorithms for the resource constraints and the power of LP for bounding the objective function.
In real-life applications, scheduling issues are often mixed with resource allocation, capacity planning, or inventory management issues for which MIP is a method of choice. Several examples have been reported where a hybrid combination of CP and MIP was shown to be more efficient than pure CP or MIP models (cf., for example, [195, 196, 94]). The generalization of these examples into a principled approach is another important research issue for the forthcoming years.
Chapter 16

Table 16.2: Activities and resources
### Table 16.3: Variables of the Constraint-Based Scheduling model

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>criterion</em></td>
<td>Variable representing the criterion to be minimized</td>
</tr>
<tr>
<td>cap(R), cap</td>
<td>Variable representing the capacity of the resource (R)</td>
</tr>
<tr>
<td>cap(A, R), cap(A)</td>
<td>Variable representing the number of units of the resource (R) required by A throughout its execution</td>
</tr>
<tr>
<td>E(A, R), E(A)</td>
<td>Variable representing the energy of the resource (R) required by A</td>
</tr>
<tr>
<td>start(A)</td>
<td>Variable representing the starting time of A</td>
</tr>
<tr>
<td>end(A)</td>
<td>Variable representing the ending time of A</td>
</tr>
<tr>
<td>proc(A)</td>
<td>Variable representing the processing time of A</td>
</tr>
<tr>
<td>altern(A)</td>
<td>Variable representing the alternative resource on which A will be executed (used only when there are alternative resources)</td>
</tr>
<tr>
<td>setup(A, A)</td>
<td>Amount of time that must elapse between the end of A and the start of A</td>
</tr>
<tr>
<td>setupCost(A, A)</td>
<td>Cost associated to the transition between A and A</td>
</tr>
<tr>
<td>set(A)</td>
<td>Variable representing the set of points at which A executes</td>
</tr>
<tr>
<td>X(A, t)</td>
<td>Binary variable that equals 1 if and only if A is in process at time t</td>
</tr>
<tr>
<td>E(A, t, R), E(A, t)</td>
<td>Variable representing the number of units of the resource (R) used by activity A at time t</td>
</tr>
</tbody>
</table>

### Table 16.4: Bounds of the variables used in the Constraint-Based Scheduling model

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>pΩ</td>
<td>Sum of the processing times p_i of activities in Ω</td>
</tr>
<tr>
<td>eΩ</td>
<td>Sum of the energies e_i of activities in Ω</td>
</tr>
<tr>
<td>rΩ</td>
<td>Smallest release date among those of activities of Ω</td>
</tr>
<tr>
<td>eetminΩ</td>
<td>Smallest value in { eet_i : A_i ∈ Ω }</td>
</tr>
<tr>
<td>dstmaxΩ</td>
<td>Largest deadline among those of activities of Ω</td>
</tr>
</tbody>
</table>

### Table 16.5: Values related to a set Ω of activities

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>domain(X)</td>
<td>Domain of the variable X</td>
</tr>
<tr>
<td>lb(X)</td>
<td>Smallest value in the domain of the variable X</td>
</tr>
<tr>
<td>ub(X)</td>
<td>Largest value in the domain of the variable X</td>
</tr>
<tr>
<td>min(S)</td>
<td>Minimal value in the set S</td>
</tr>
<tr>
<td>max(S)</td>
<td>Maximal value in the set S</td>
</tr>
<tr>
<td>length(I)</td>
<td>Length of the interval I</td>
</tr>
</tbody>
</table>

### Table 16.6: Basic notations
<table>
<thead>
<tr>
<th>Symbol</th>
<th>Definition</th>
</tr>
</thead>
</table>
| $W_{PE}(A_i,t_1,t_2)$ | Energy consumption of $A_i$ over $[t_1,t_2]$ (preemptive case)  
$= c_i \max(0,p_i - \max(0,t_1 - r_i) - \max(0,d_i - t_2))$ |
| $W_{PE}(t_1,t_2)$ | Overall required energy consumption over $[t_1,t_2)$  
$= \sum_i W_{PE}(A_i,t_1,t_2)$ |
| $S_{PE}(t_1,t_2)$ | Slack over $[t_1,t_2)$ (preemptive case)  
$= C(t_2 - t_1) - W_{PE}(t_1,t_2)$ |
| $p_i^+(t_1)$ | Minimal number of time units during which $A_i$ must execute after $t_1$  
$= \max(0,p_i - \max(0,t_1 - r_i))$ |
| $p_i^-(t_2)$ | Minimal number of time units during which $A_i$ must execute before $t_2$  
$= \max(0,p_i - \max(0,d_i - t_2))$ |
| $W_{Sh}(A_i,t_1,t_2)$ | Energy consumption of $A_i$ over $[t_1,t_2)$ (non-preemptive case)  
$= c_i \min(t_2 - t_1,p_i^+(t_1),p_i^-(t_2))$ |
| $W_{Sh}(t_1,t_2)$ | Overall required energy consumption over $[t_1,t_2)$  
$= \sum_i W_{Sh}(A_i,t_1,t_2)$ |
| $S_{Sh}(t_1,t_2)$ | Slack over $[t_1,t_2)$ (non-preemptive case)  
$= C(t_2 - t_1) - W_{Sh}(t_1,t_2)$ |
