HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
RÉPICATION ASYNCHRONE DES DONNÉES DANS TROIS CONTEXTES:
entrepôts, grappes et systèmes pair-à-pair

ESTHER PACITTI
8 JUILLET 2008
I want to thank all the people I met (so many friends) at all the institutions I worked for, which motivated my whole research work since I started in Brazil in 1985: Federal University of Rio de Janeiro (NCE and COPPE), Pontifícia Universidade Católica do Rio de Janeiro (PUC-Rio), University of Paris 5, INRIA (many many thanks to the INRIA teams Rodin, Caravel and Atlas) and University of Nantes. I am very grateful to Brazilian university leaders who always encouraged my research and pushed me to come to France for my Ph.D., providing me a fellowship and believing in me. I very much appreciated this. More recently, the people involved in the management of LINA, Prof. Frédéric Benhamou, Prof. Noureddine Mouaddib and Prof. Pierre Cointe encouraged my research on data replication. I am also very thankful to INRIA, with which I have been involved since 1995 (as a Ph.D. student) until today, as a member of the Atlas team, for providing an excellent environment to do research. In particular, my recent “delegation” at INRIA was crucial to help me produce this HDR report.

Many thanks to the committee members: Prof. Anne Doucet (rapporteur), Prof. Philippe Pucheral (rapporteur), Prof. Michel Scholl (rapporteur), Dr. Serge Abiteboul (examineur), Prof. Noureddine Mouaddib (examineur), Prof. (examineur) for their interest in my work. Special thanks to Anne Doucet for helping in organizing the HDR defense.

I also want to express my intense gratitude to the researchers who helped me during critical times of my research path: Prof. Tamer Özsu, Dr. Eric Simon, Prof. Dennis Shahsa, Prof. Ricardo Jimenez-Peris and Dr. Patrick Valduriez. I am also very thankful to Prof. Bettina Kemme who kindly helped in reviewing this report.

I am very thankful to the members of the Atlas team who contributed to the research in data replication during our thursday meetings, providing useful suggestions and coming up with very good questions. In particular, I am grateful to the Ph.D. students whom I had the chance and pleasure to work with: Cédric Coulon, Vidal Martins, Reza Akbarinia, Manal-El-Dick, Wence Palma. I would also like to thank Elodie Lize for her kind assistance on the defense organization.

And last but not least, I would like to thank my Brazilian and French families for believing and loving me, especially my husband Patrick and daughter Anna.

Making research is sometimes very hard but we also can have much fun!

**Résumé Etendu**

**Motivations**

Dans une base de données distribuée, la réplication de données permet d’augmenter la fiabilité et la disponibilité des données ainsi que les performances d’accès [SS05]. En général, l’unité (ou l’objet) de réplication est une table relationnelle (ou un fragment de table), un document ou un fichier. La réplication consiste alors à placer plusieurs copies (ou répliques) de l’objet sur différents nœuds du réseau. Cela fournit une grande disponibilité des données. Si un nœud devient non opérationnel à la suite d’une panne par exemple, une autre copie est toujours accessible sur un autre nœud. La réplication permet aussi d’améliorer les performances d’accès en augmentant la localité de référence. Lorsque le coût de communication est un facteur dominant, le placement d’une copie sur le nœud où elle est le plus souvent accédée favorise les accès locaux et évite les accès réseaux.

Les avantages apportés par la réplication sont à comparer avec la complexité et les coûts supplémentaires de maintenance des copies qui doivent, en théorie rester identiques à tout moment. La mise-à-jour d’une copie doit être répercutée automatiquement sur toutes ses répliques. Le problème est compliqué par la présence de pannes de nœud ou réseau. Le compromis recherché entre performance d’accès en consultation et en mise-à-jour des données rend difficile le choix du niveau de réplication. Celui-ci est très dépendant de la charge de travail demandée par les applications. Le problème de la réplication de données reste donc un vaste thème de recherche et les solutions doivent être adaptées au contexte afin d’offrir un bon compromis entre des objectifs conflictuels tels que disponibilité, cohérence, performances, etc. Dans mon travail de recherche, je me suis concentrée sur le maintien de la cohérence des données répliquées dans trois contextes majeurs: les entrepôts de données, les grappes de bases de données, et les applications collaboratives en pair-à-pair (P2P).

**Entrepôts de Données**

Dans les entrepôts de données [Cod95], la configuration mono-maître est souvent utilisée, avec diverses variantes possibles: diffusion, mono-consolidation (consolidation avec un nœud), multi-consolidation (avec plusieurs nœuds), triangulaire. La gestion de la cohérence est difficile pour certaines configurations comme la consolidation avec plusieurs nœuds, la configuration triangulaire ou leurs généralisations en combinant les configurations de base.
Grappes de bases de données

Les grappes de bases de données (database clusters) sont typiquement utilisées par des applications de lectures intensives, ce qui facilite l'exploitation du parallélisme. Cependant, les grappes [ABKW98] peuvent également être utilisées par des applications avec beaucoup de mises-à-jour, par ex. par un ASP (Application Service Provider). Dans un contexte ASP, les applications et les bases de données des clients sont stockées chez le fournisseur et sont disponibles, typiquement depuis Internet, aussi efficacement que si elles étaient locales pour les clients. Pour améliorer les performances, les applications et les données peuvent être répliquées sur plusieurs nœuds. Ainsi, les clients peuvent être servis par n'importe quel nœud en fonction de la charge. Cette architecture fournit une haute disponibilité: dans le cas de la panne d'un nœud, d'autres nœuds peuvent effectuer le même travail. Le défi est alors de gérer la réplication multi-maître, totale et partielle, en assurant la cohérence forte et le passage à l’échelle en nombres de nœuds.

Applications Collaboratives en P2P

Les systèmes P2P adoptent une approche complètement décentralisée [AMPV06a] au partage des ressources. En distribuant données et traitements sur tous les pairs du réseau, ils peuvent passer à très grande échelle sans recourir à des serveurs très puissants. La réplication de données dans les systèmes P2P [AMPV04] est un enjeu majeur pour les applications collaboratives, comme les forums de discussion, les calendriers partagés, ou les catalogues de e-commerce, etc. En effet, les données partagées doivent pouvoir être mises-à-jour en parallèle par différents pairs. Les premiers systèmes P2P existants supposent que les données sont statiques et n'intègrent aucun mécanisme de gestion des mises-à-jour et de réplication. Une mise-à-jour d'une donnée par le pair qui la possède implique une nouvelle version non propagée à ceux répliquant cette donnée. Il en résulte diverses versions sous le même identifiant et l'utilisateur accède à celle stockée par le pair qu'il contacte. Aucune forme de cohérence entre les répliques n'est alors garantie. Le défi est de gérer la cohérence éventuelle face au dynamisme des pairs tout en passant à l’échelle.

Contributions

Les contributions de recherche présentées dans ce rapport scientifique correspondent à la période 1999-2008 :

2. Réplication multi-maître dans les grappes de bases de données (2002-2005). Nous avons proposé un nouvel algorithme de réplication de données, dit préventif, asynchrone et multi-maître qui assure la cohérence forte dans les grappes de bases de données [POC03, CGPV04, CPV05a, CPV05b, PCVO05]. Ce travail a été validé dans le cadre du projet RNTL Leg@net avec le prototype RepDB*.

3. Réconciliation de données dans les applications collaboratives en P2P (2006-2008). Nous avons proposé des algorithmes efficaces pour la gestion de données répliquées en P2P, notamment pour la réconciliation de données répliquées en mode optimiste [AMPV04, MPV05, MPJV06, MAPV06, MP06, AMPV06a, MPV06b, EPV07, MPEJ08]. Nous avons aussi proposé des optimisations qui exploitent la localité offerte par certains réseaux P2P. Nous avons validé ces algorithmes avec le prototype APPA, dans le cadre des ACI Masses de Données MDP2P et Respire, le projet européen STREP Grid4All et le projet RNTL Xwiki Concerto.

4. Gestion de données courantes dans les DHTs répliqués (2007-2008). Nous avons proposé une solution complète pour déterminer les données courantes (les plus à jour) parmi les données répliquées dans les tables de hachage distribuées (DHTs) [APV07a]. Nous avons validé notre solution par une implémentation du DHT Chord sur un cluster de 64 nœuds et par une simulation jusqu'à 10.000 pairs en utilisant SimJava. Ce travail a été réalisé dans le cadre de l’ACI Masses de Données Respire.

Ces travaux ont été aussi validés par deux prototypes majeurs qui implémentent les techniques proposées :

Système de gestion de données pair-à-pair pour des applications collaboratives, en cours de réalisation en Java sous OpenChord. En particulier, nous développons le nouveau service P2P-LTR (P2P Log and Timestamping for Reconciliation) qui permet la réconciliation pour l’édition collaborative.

**Réplication Mono-Maître dans les Entrepôts de Données**

Dans le contexte des entrepôts de données, qui servent principalement à la prise de décision, un objectif majeur est de concevoir des algorithmes de maintien de la cohérence des données répliquées : en minimisant le degré de fraîcheur ; en minimisant la surcharge de messages (éviter les votes) ; en étant assez extensible pour différentes configurations ; en tolérant les pannes des nœuds.

La minimisation du degré de fraîcheur compense la perte de la cohérence mutuelle due à la réplication asynchrone (car il y a perte de cohérence mutuelle). Les solutions existantes pour la gestion de la cohérence pour la réplication mono-maître sont spécifiques pour certaines configurations. La gestion de la cohérence est une tâche difficile lorsque le placement des données détermine le routage des messages et qu’un nœud tombe en panne. L’idée d’utiliser, de façon contrôlée, les services du réseau est alors très utile pour la réplication asynchrone. C’est la voie de recherche que nous avons choisie. Au-delà des algorithmes proposés, nous avons aussi proposé une architecture qui respecte l’autonomie des SGBD (vus comme des boîtes noires) et donc fonctionne avec tout type de SGBD.

**Gestion de la Fraîcheur**

Pour certaines applications, par ex. boursières, il est très important de minimiser le degré de fraîcheur entre copies primaires (les copies en mise-à-jour) et copies secondaires (les copies en lecture seule). C’est pourquoi l’approche push, où les mises-à-jour sont envoyées par les nœuds maîtres (stockant des copies primaires), a été choisie. Un premier objectif est alors de minimiser le degré de fraîcheur pour les configurations de type diffusion et mono-consolidation.

Dès qu’une transaction $T$ de mise-à-jour est validée sur le maître, ses mises-à-jour sont propagées vers les nœuds cibles dans un message, en différé. On appelle cette stratégie de propagation différé-différé. Pour minimiser le degré de fraîcheur, nous avons proposé la propagation immédiate. L’idée est de propager les opérations de mises-à-jour d’une transaction $T$, qui met à jour une relation $R$, dès que la première opération d’écriture (noté $w$) sur $R$ est
détectée. Pour garantir la sérialisabilité des opérations d’écriture, nous utilisons la primitive de réseau FIFO [HT93]. Pour le nœud cible, trois stratégies de réception sont possibles [PSM98]:

- **immédiate**: dès que la première opération d’écriture $w$ arrive, la transaction de mise-à-jour sur la copie secondaire $r$ est déclenchée, mais seulement validée après la réception du commit de $T$.

- **différé**: le nœud cible attend la réception complète de la transaction (toutes les opérations une par une) puis déclenche la transaction sur $r$.

- **à posteriori**: le nœud cible attend la réception complète de la transaction, puis (à la réception) déclencher la transaction sur $r$.

La combinaison de la stratégie de propagation immédiate avec les stratégies de réception produisent trois stratégies: immédiate-immédiate, immédiate-différé, immédiate-posteriori. Nos résultats de performance (obtenus par simulation) ont montré que les stratégies immédiates peuvent améliorer jusqu’à 5 fois le degré de fraîcheur comparé à la stratégie différé-différé. De plus, le traitement de la tolérance aux pannes des nœuds peut être facilement implémenté en utilisant des journaux, sans bloquer les protocoles de réplication. L’Annexe A présente les détails de ces contributions qui correspondent à la publication [PS00].

### Gestion de la Cohérence des Données

Certaines architectures d’entrepôts de données mettent en œuvre des configuration de réplication de type multi-consolidation et triangulaire. Un problème important est alors d’assurer la cohérence sans imposer un chemin de routage pour les transactions de mise-à-jour. Pour les configurations triangulaires, la propriété de causalité doit aussi être assurée. La diffusion FIFO ne suffit plus pour assurer la cohérence. Pour résoudre ce problème, nous avons proposé d’utiliser des estampilles avec les services de réseau.

Bien que les services de réseau soient très attractifs, le nombre de messages augmente considérablement pour augmenter les garanties, limitant ainsi le passage à l’échelle. C’est pourquoi nous avons évité la primitive *ordre total* (très chère en messages) et utilisé la primitive FIFO (beaucoup plus efficace). Pour garantir l’ordre total, des estampilles globales $C$ sont données aux transactions de mise-à-jour au moment de la validation de chaque transaction sur les nœuds maîtres. Pour cela, on suppose un système semi-asynchrone où les horloges sont $\varepsilon$-synchronisés et le temps de transmission maximal d’un message ($Max$) est connu [BGM04]. Pour gérer la cohérence des copies sur les nœuds cible, nous avons proposé l’algorithme *refresher* [PMS99, PMS01].
Les transactions de mises-à-jour sont exécutées sur le noeud maître puis sont propagées à toutes les copies sous forme de transactions de rafraîchissement. À la réception de l'une de ces transactions, le noeud cible place la transaction dans une file d'attente (il y a une file d'attente par maître que possède la copie primaire). La transaction de rafraîchissement attend alors un temps $\text{Max}$ avant d'être élu et placée dans une file d'exécution. En attendant un temps $\text{Max}$ après son départ, on s'assure alors qu'aucun message n'a été émis auparavant et transite encore sur le réseau (le réseau est fiable et un message met au maximum un temps $\text{Max}$ pour arriver à destination). Le moment exact où le message sera élu pour exécution est donc: $C + \text{Max} + \varepsilon$. Cet algorithme assure l'ordre total des transactions de rafraîchissement. L’Annexe B présente les détails de ces contributions qui correspond à la publication [PMS01]

**Réplication Multi-Maître dans les Grappes de Bases de Données**

Pour les grappes de bases de données, nous avons adopté la réplication multi-maître qui permet de mettre à jour en parallèle (sur différents nœuds) les copies d’un même objet et ainsi de maximiser les performances. Nous avons proposé un nouvel algorithme de réplication préventif, en partant de l'algorithme refresher. Le principe de l'algorithme refresher est de soumettre les transactions dans un ordre total sur les nœuds cibles en fonction de leur estampille d'arrivée. Pour accomplir ceci, le nœud cible retarde l'exécution des transactions pour s'assurer qu'aucune transaction plus ancienne n'est en route vers le nœud. Cependant, cet algorithme n'autorise que la mise-à-jour sur un seul nœud (mono-maître). Nous abordons donc le problème où plusieurs maîtres peuvent faire des mises jour en parallèle.

**Réplication Preventive**

La réplication préventive [POC03, PCVO05] assure la cohérence forte (il n’y a jamais d’incohérences) pour les configurations multi-maîtres (en réplication totale et partielle). Pour la réplication totale (les données sont répliquées sur tous les nœuds), lorsqu’une transaction $T$ arrive dans la grappe elle est diffusé en FIFO à tous les nœuds de la grappe y compris le nœud qui a reçu la transaction. Chaque nœud de la grappe retarde l’exécution de $T$, comme auparavant, et la cohérence forte est assurée pour les mêmes raisons. En autorisant ainsi davantage de nœuds multi-maîtres, nous supprimons le goulot d'étranglement que représente un seul nœud maître. Cependant, le surcôt en mise-à-jour sur tous les nœuds peut être important, d'où la nécessité de la réplication partielle (les données sont répliquées sur certains nœuds).

Pour la réplication partielle [CPV05a, CPV05b], nous ne faisons pas de restrictions ni sur le type de copies (copie primaire ou multi-maître) ni sur le placement des données (un nœud peut...
posséder une partie seulement des copies et plusieurs types de copie: primaire, multi-maître, secondaire). Cependant, un noeud peut ne pas être en mesure d’exécuter toutes les transactions car il ne possède pas toutes les copies nécessaires. L’algorithme place alors la transaction en attente des jeux d'écritures qui sont diffusés par le noeud d'origine. L'algorithme de réplication partielle autorise donc un plus grand nombre de configurations mais introduit la diffusion d'un message de rafraîchissement.

Pour chacune des versions de l'algorithme de réplication préventive (totale et partielle), nous avons proposé: une architecture pour le gestionnaire de réplication, une description détaillée des algorithmes et les preuves que ces algorithmes garantissent la cohérence forte sans introduire d'inter-blocages.

**Optimisations**

Afin de mieux supporter les applications à fortes charges transactionnelles où les mise-à-jour sont majoritaires, nous avons amélioré l'algorithme de réplication préventive. Nous avons dans un premier temps éliminé le délai introduit par l'ordonnancement des transactions en les exécutant de manière optimiste dès leur réception dans le noeud et non plus après le délai $\text{Max} + \varepsilon$. Si les transactions n'ont pas été exécutées dans l'ordre correct (celui de leurs estampilles), alors elles sont annulées et ré-exécutées après ordonnancement. Le nombre d'abandons reste faible car dans un réseau rapide et fiable les messages sont naturellement ordonnés [PS98]. Avec cette optimisation, la cohérence forte est garantie car nous retardons la validation des transactions (et non plus la totalité de la transaction) exécutées de façon optimiste. Les transactions sont ordonnancées pendant leur exécution et non plus avant, supprimant ainsi les délais d'ordonnancement.

La seconde optimisation concerne la soumission des transactions. Dans les algorithmes précédents, les transactions sont soumises à exécution une par une pour garantir la cohérence. Le module de soumission représente donc un goulot d'étranglement dans le cas où le temps moyen d'arrivée des transactions est supérieur au temps moyen d'exécution d'une transaction. Pour supprimer ce problème, nous avons autorisé l'exécution parallèle des transactions non conflictuelles. Cependant, pour garantir la cohérence des données, nous ordonnancions toujours le démarrage et la validation des transactions, ceci afin de garantir que toutes les transactions soient exécutées dans le même ordre sur tous les noeuds malgré le parallélisme. Nous avons prouvé que l'exécution en parallèle des transactions est équivalente à une exécution séquentielle. L’Annexe C présente les détails de ces contributions qui correspond à la publication [PCVO05].
Validation
Nous avons validé l'algorithme de réplication préventive en testant trois propriétés recherchées pour un algorithme de réplication asynchrone en grappe:

- **Le passage à l'échelle.** Nous avons montré que l'augmentation du nombre de noeuds n'influence pas les performances quelque soient la charge et la configuration. Nous avons également montré l'influence de la configuration sur les temps de réponse. Quand la configuration et le placement des données sont adaptés au type de transactions soumises au système alors les performances deviennent optimales.

- **Les gains en performances.** Si les performances ne se dégradent pas pour les transactions de mises-à-jour lorsqu'on augmente le nombre de noeuds, le débit du système pour les lectures augmente.

- **Le degré de fraîcheur**: le retard en nombre de validations de transactions reste toujours faible quelque soit le banc d'essai et la configuration. C'est lorsque les transactions ne sont pas adaptées aux types de configurations que le degré de fraîcheur diminue. Dans ce cas certains noeuds (ceux qui possèdent le plus de copies) sont plus chargés que d'autres et mettent plus de temps à exécuter toutes les transactions qui leur sont soumises.

De plus, nous avons montré que nos optimisations permettent un meilleur support face aux fortes charges. En effet, en exécutant les transactions en parallèle et en éliminant le délai d'ordonnancement, notre système supporte mieux l'émission massive de transactions. Les expérimentations ont prouvé que l'exécution optimiste des transactions n'entraînait un taux très faible d'abandons (1%), ce qui rend notre optimisation viable. Finalement, nous avons développé le prototype RepDB* [CGPV04] qui implémente l'algorithme de réplication préventive avec toutes les optimisations.

Réconciliation de Données pour les Application Collaboratives en P2P
Les wikis sont maintenant très utilisés pour l'édition collaborative de documents sur le Web mais s'appuient sur un site central, qui peut être un goulot d'étranglement et un point critique en cas de panne. Une approche P2P permet de pallier à ces problèmes et offre d'autres avantages comme un meilleur contrôle des données privées (qui restent locales) et le support du travail en mode déconnecté. A partir d'une application de Wiki en P2P [Wik07], nous pouvons résumer les besoins de réplication pour les applications collaboratives comme suit : haut niveau d'autonomie, réplication multi-maître, détection et résolution de conflits, cohérence éventuelle des répliques, et indépendance des types de données.
La réplication optimiste supporte la plupart de ces besoins en permettant la mise-à-jour asynchrone des répliques de sorte que les applications puissent progresser même si quelques nœuds sont déconnectés ou en panne. En conséquence, les utilisateurs peuvent collaborer de manière asynchrone. Cependant, les solutions optimistes existantes sont peu applicables aux réseaux P2P puisqu’elles sont centralisées ou ne tiennent pas compte des limitations du réseau. Les approches centralisées sont inadéquates en raison de leur disponibilité limitée et de leur vulnérabilité aux fautes et aux partitions du réseau. D’autre part, les latences variables et les largeurs de bande, typiques des réseaux P2P, peuvent fortement influencer sur les performances de réconciliation puisque les temps d’accès aux données peuvent changer de manière significative de nœud à nœud. Par conséquent, afin d’établir une solution appropriée de réconciliation P2P, des techniques optimistes de réplication doivent être revues.

Motivé par ce besoin, nous avons proposé une solution hautement disponible de réconciliation et qui passe à l’échelle pour des applications de collaboration P2P. Pour ce faire, nous proposons des protocoles de réconciliation basés sur la sémantique qui assurent la cohérence éventuelle des répliques et tiennent compte des coûts d’accès aux données.

**Réconciliation Sémantique Distribuée (DSR)**

L'algorithme DSR (*Distributed Semantic Reconciliation*) [MPV05] utilise le modèle *action-contrainte* proposé pour le système IceCube [KRSD01, PSM03, SBK04] afin de capturer la sémantique de l'application et résoudre les conflits de mise-à-jour. Cependant, DSR est tout à fait différent d'IceCube car il adopte des hypothèses différentes et fournit des solutions distribuées. Dans IceCube, un seul nœud centralisé prend des actions de mise-à-jour de tous les autres nœuds pour produire un ordonnancement global. Ce nœud peut être un goulot d'étranglement. D'ailleurs, si le nœud qui fait la réconciliation tombe en panne, le système entier de réplication peut être bloqué jusqu'au rétablissement. En revanche, DSR est une solution répartie qui tire profit du traitement parallèle pour fournir la haute disponibilité et le passage à l’échelle.

Nous avons structuré l'algorithme DSR en 5 étapes reparties pour maximiser le traitement parallèle et pour assurer l'indépendance entre les activités parallèles. Cette structure améliore les performances et la disponibilité de la réconciliation (c.-à-d. si un nœud tombe en panne, l'activité qu'il était en train d’exécuter est attribuée à un autre nœud disponible).

Avec DSR, la réplication de données se passe comme suit. D'abord, les nœuds exécutent des actions locales pour mettre à jour une réplique d'un objet tout en respectant des contraintes définies par l'utilisateur. Puis, ces actions (avec les contraintes associées) sont stockées dans une
table de hachage distribuée (DHT) en se basant sur l'identifiant de l'objet. Enfin, les nœuds réconciliateurs retrouvent les actions et les contraintes dans la DHT et produisent un ordonnancement global en réconciliant les actions conflictuelles. Cette réconciliation est complètement distribuée et l'ordonnancement global est localement exécuté dans chaque nœud, assurant de ce fait la cohérence éventuelle [SBK04, SS05].

Dans cette approche, nous distinguons trois types de nœuds : le nœud de réplique, qui tient une réplique locale ; le nœud réconciliateur, qui est un nœud de réplique qui participe à la réconciliation distribuée ; et le nœud fournisseur, qui est un nœud dans la DHT qui stocke des données consommées ou produites par les nœuds réconciliateurs (par ex., le nœud qui tient l’ordonnancement s'appelle le fournisseur d’ordonnancement).

Nous concentrons le travail de réconciliation dans un sous-ensemble de nœuds (les nœuds réconciliateurs) pour maximiser les performances. Si nous ne limitons pas le nombre de nœuds réconciliateurs, les problèmes suivants peuvent survenir. D'abord, les nœuds fournisseurs et le réseau entier deviennent surchargés à cause d’un grand nombre de messages visant à accéder au même sous-ensemble d’objets dans la DHT pendant un intervalle très court de temps. Ensuite, les nœuds avec de hautes latences et de faibles bandes passantes peuvent gaspiller beaucoup de temps avec le transfert de données, compromettant de ce fait le temps de réconciliation. Notre stratégie ne crée pas des déséquilibres dans la charge des nœuds réconciliateurs car les activités de réconciliation ne sont pas des processus intensifs.

Réconciliation P2P (P2P-Reconciler)

*P2P-reconciler* transforme l'algorithme DSR en protocole de réconciliation en développant des fonctionnalités additionnelles que DSR ne fournit pas. D'abord, il propose une stratégie pour calculer le nombre de nœuds qui devraient participer à la réconciliation afin d'éviter des surcharges de messages et assurer de bonnes performances [MAPV06, MPV06a]. En second lieu, il propose un algorithme distribué pour choisir les meilleurs nœuds réconciliateurs basés sur les coûts d'accès aux données, qui sont calculés selon les latences de réseau et les taux de transfert. Ces coûts changent dynamiquement pendant que les nœuds rejoignent et partent du réseau, mais notre solution fait face à un tel comportement dynamique. Troisièmement, il garantit la cohérence éventuelle des répliques en dépit de jonctions et départs autonomes des nœuds [MAPV06, MP06, MPV06a, MPJV06]. En outre, nous avons formellement montré que P2P-reconciler assure la cohérence éventuelle, est fortement disponible, et fonctionne correctement en présence des fautes.
Réconciliation consciente de la topologie (P2P-reconciler-TA)

*P2P-reconciler-TA* [EMP07] est une optimisation du protocole P2P-reconciler qui vise à exploiter les réseaux P2P conscients de leurs topologies (en anglais, *topology-aware P2P networks*) pour améliorer les performances de réconciliation. Les réseaux P2P conscients de leurs topologies établissent les voisinages parmi les nœuds basés sur des latences de sorte que les nœuds qui sont proches les uns des autres en termes de latence dans le réseau physique soient aussi des voisins dans le réseau P2P logique. Pour cette raison, des messages sont routés plus efficacement sur les réseaux conscients de leurs topologies. L'algorithme DSR n'est pas affecté par la topologie du réseau. Cependant, un autre algorithme est nécessaire pour le choix des nœuds qui participent à la réconciliation.

Plusieurs réseaux P2P conscients de leurs topologies peuvent être employés pour valider notre approche telle que Pastry [RD01a], Tapestry [ZHSR+04], CAN [RFHK+01], etc. Nous avons choisi CAN parce qu'il permet de construire le réseau P2P logique conscient de sa topologie d'une façon assez simple. De plus, il est facile de mettre en œuvre son mécanisme de routage, bien que moins efficace que d'autres réseaux P2P conscients de leurs topologies (par ex., le chemin de routage moyen dans CAN est habituellement plus long que dans d'autres réseaux P2P structurés).

Validation
Nous avons validé nos algorithmes par la création d’un prototype et d’un simulateur. Le prototype sur la plateforme distribuée Grid5000 nous a permis de vérifier l'exactitude de notre solution de réplication et de calibrer le simulateur. D'autre part, le simulateur a permis d'évaluer le comportement de notre solution sur des réseaux plus grands. L'évaluation de performances de DSR a montré qu'il surpasse la réconciliation centralisée en réconciliant un grand nombre d'actions. En outre, il fournit un plus grand degré de disponibilité, de passage à l'échelle, et de tolérance aux fautes. D'ailleurs, il passe à l'échelle très bien jusqu'à 128 nœuds réconciliateurs. Puisque le nombre de nœuds réconciliateurs ne limite pas le nombre de nœuds de répliques, il s'agit d’un excellent résultat.

P2P-reconciler a été évalué avec des méthodes distinctes d’allocation de nœuds réconciliateurs. Les résultats expérimentaux ont prouvé que la réconciliation avec l'allocation basée sur le coût surpasse l'approche aléatoire par un facteur de 26. De plus, le nombre de nœuds connectés n'est pas important pour déterminer les performances de réconciliation. Ceci est du au fait que la DHT passe à l'échelle et les réconciliateurs sont aussi proches que possible des objets de réconciliation. Par ailleurs, la taille des actions affecte le temps de réconciliation dans une échelle logarithmique. En conclusion, P2P-reconciler restreint la surcharge du système puisqu'il calcule des coûts de communication en employant des informations locales et limite la portée de la propagation des événements (par ex., jonction ou départ).

Nos résultats expérimentaux ont prouvé que P2P-reconciler-TA sur CAN surpasse P2P-reconciler par un facteur de 2. C'est un excellent résultat si nous considérons que P2P-reconciler est déjà un protocole efficace et CAN n'est pas le réseau P2P conscient de topologie le plus efficace (par ex., Pastry et Tapestry sont plus efficaces que CAN). P2P-reconciler-TA exploite d'une manière très appropriée les réseaux conscients de topologie puisque ses meilleures performances sont obtenues quand le degré de proximité parmi les nœuds en termes de latence est le plus élevé. De plus, il passe à l'échelle au fur et à mesure que le nombre de nœuds connectés augmente. En conclusion, l'approche heuristique de P2P-reconciler-TA pour choisir les nœuds réconciliateurs est très efficace.

Gestion de Données Courantes dans les DHTs Répliquées
Les DHTs, comme CAN [RFHKS01] et Chord [SMKK+01], fournissent une solution efficace pour la recherche de données dans les systèmes P2P. Une DHT réalise une conversion entre une clé $k$ et un pair $p$, appelé le responsable pour $k$, en utilisant une fonction de hachage, et permet
ainsi de trouver efficacement le pair qui est responsable pour une clef. Les DHTs fournissent typiquement deux opérations de base [HHHL+02]: put \((k, \text{data})\) stocke une clef \(k\) et une donnée \text{data} dans la DHT en utilisant une fonction de hachage; get \((k)\) recherche la donnée stockée dans la DHT avec la clef \(k\). Cependant, la disponibilité des données stockées n’est pas garantie. Pour améliorer la disponibilité des données, nous pouvons répliquer la paire \((k, \text{data})\) sur plusieurs pairs. Toutefois, la cohérence des répliques après mise-à-jour peut être compromise en raison des pairs qui ont quitté le réseau ou des mises-à-jour concurrentes.

Nous avons proposé une solution complète pour déterminer les données courantes (les plus à jour) parmi les données répliquées dans les DHTs [APV07a]. Cette solution consiste en un service de gestion des mises-à-jour, UMS (**Update Management Service**), qui permet de gérer des données répliquées et de retrouver les copies courantes (les plus à jour). Pour ce faire, UMS s’appuie sur un service d'estampillage basé sur clef, KTS (**Key-based Timestamp Service**), qui permet de générer des estampilles logiques d’une façon complètement distribuée.

**Gestion des Mises-à-jour (UMS)**

UMS permet d’insérer (opération insert) une donnée et sa clef en la répliquant dans la DHT et de retrouver (opération retrieve) la donnée répliquée la plus courante correspondant à une clef donnée. Le fonctionnement de UMS peut être résumé comme suit. Soit \(H\) un ensemble de fonctions de hachage. Pour chaque clef \(k\) et chaque fonction de hachage \(h\), il y a un pair \(p\) responsable pour \(k\). Nous appelons \(p\) le responsable de \(k\) par rapport à \(h\), et le dénotons par \(\text{rsp}(k, h)\). Un pair peut être responsable pour \(k\) par rapport à une fonction \(h_1\) mais non responsable pour \(k\) par rapport à une autre fonction \(h_2\). Pour améliorer la disponibilité des données, le service UMS stocke chaque donnée sur plusieurs pairs en utilisant un ensemble de fonctions de hachage \(\mathcal{H}_r \subset H\). l'ensemble \(H\), s'appelle l'ensemble de fonctions de réplication. Le nombre de fonctions de réplication, c.-à-d. \(|\mathcal{H}_r|\), peut être différent pour différents réseaux P2P.

Des répliques peuvent devenir obsolètes, par exemple en raison de l'absence de certains pairs au moment de la mise-à-jour. Afin de distinguer entre les répliques courantes (à jour) et obsolètes, avant de stocker les données, UMS leur ajoute une estampille logique qui est produite par le service KTS. En prenant une clef \(k\) et une donnée \text{data}, pour chaque \(h \in \mathcal{H}_r\), UMS stocke \((k, \{\text{data, estampille}\})\) sur le pair \(\text{rsp}(k, h)\). Suite à une demande pour une donnée qui est stockée avec une clef sur la DHT, UMS renvoie l'une des répliques qui a une estampille récente.
Estampillage (KTS)

L'opération principale de KTS est l'opération \textit{gen\_ts} (\(k\)) qui, en prenant une clef \(k\), produit un nombre réel en tant qu'estampille pour \(k\). Les estampilles produites par KTS ont la propriété de monotonie, c.-à-d. que les estampilles produites pour la même clef sont monotonement croissantes.

KTS produit les estampilles d'une façon complètement distribuée, en utilisant les compteurs locaux. A chaque moment, il produit au maximum une estampille pour une clef \(k\). Donc, en considérant la propriété de monotonie, il y a un ordre total sur l'ensemble des estampilles produites pour une clef. Cependant, il n'y a aucun ordre total sur les estampilles produites pour des clefs différentes. En plus de \textit{gen\_ts}(\(k\)), KTS a une autre opération dénotée par \textit{last\_ts} (\(k\)) qui en prenant une clef \(k\), renvoie la dernière estampille produite pour \(k\).

L'opération \textit{gen\_ts}(\(k\)) produit des estampilles monotonement croissantes pour les clefs. Une solution centralisée pour produire les estampilles n'est évidemment pas viable dans un système P2P car le pair central serait un goulot d'étranglement et un point d'échec. Et les solutions distribuées à l'aide d'horloges synchronisées ne s'appliquent pas non plus dans un système P2P.

Nous avons proposé alors une technique distribuée pour produire des estampilles dans les DHTs. Elle utilise des compteurs locaux pour produire des estampilles et des algorithmes d'initialisation des compteurs qui garantissent la monotonie des estampilles, même en cas de pannes. L'Annexe E présente les détails de toutes ces contributions qui correspond à la publication [APV07a].

Validation

Nous avons validé notre solution par une implémentation sur un cluster de 64 nœuds de Grid5000 et par une simulation jusqu'à 10.000 pairs en utilisant SimJava [HM98]. Nous avons réalisé les services UMS et KTS sur notre propre implémentation de Chord [SMKK+01], une DHT simple et efficace.

Nous avons comparé les performances de notre service UMS avec celles de BRK (un service réalisé dans le projet BRICK [KWR05]). Les résultats d'expérimentation et de simulation montrent que KTS et UMS donnent des gains majeurs, en termes de temps de réponse et de coût de communication, par rapport à BRK. Le temps de réponse et le coût de communication d'UMS ont une tendance logarithmique en nombre de pairs de la DHT. L'augmentation du nombre de répliques n'a pas d'impact sur le temps de réponse et le coût de communication de UMS. Mais cette augmentation a un grand impact négatif sur BRK. Nous avons aussi testé UMS et KTS dans des situations où la DHT est très dynamique, c.-à-d. les
pairs rejoignent et quittent le système fréquemment. Les résultats ont montré que même dans ces situations, UMS et KTS fonctionnent très bien. En résumé, notre validation a montré que la gestion des données courantes peut être supportée efficacement dans les DHTs.

Conclusions et Travaux Futurs

Dans le contexte des *entrepôts de données*, nous avons proposé des algorithmes pour la gestion de la cohérence pour la réplication asynchrone mono-maître. Le principe de l'algorithme *refresher* est de soumettre les transactions dans un ordre total sur tous les nœuds cibles en fonction de leur estampille d'arrivée. Pour ce faire, l'algorithme refresher retarde (avec un délai d’attente) l’exécution des transactions pour s’assurer qu’aucune transaction plus ancienne n’est en route pour le nœud. L'algorithme refresher impose une restriction sur le placement des données (le graphe de dépendances des nœuds ne doit pas former de cycles). Nos résultats de performance (obtenus par simulation) ont montré que des stratégies immédiates peuvent améliorer jusqu’à 5 fois le degré de fraîcheur comparé à des stratégies différées.

Dans le contexte des *grappes de bases de données*, nous avons présenté un nouvel algorithme de réplication dite *préventive*, basés sur l'algorithme *refresh*. Nous avons ajouté le support de la réplication totale et partielle ainsi que d’importantes optimisations pour relâcher les délais d’attente. Nous avons montré que ces algorithmes avaient de très bonnes performances et passaient à l’échelle. Nous avons réalisé ces algorithmes dans le prototype RepDB* avec les SGBD PostGreSQL et BerkeleyDB.

Nous avons aussi proposé une solution complète au problème d’accès à des données courantes dans les DHTs [APV07a]. Nous avons proposé le service UMS qui permet de mettre à jour les données répliquées et l’accès efficace à des répliques courantes en utilisant une approche basée sur l’estampillage. Après la récupération d’une réplique, UMS détecte si elle est
courante ou pas, c.-à-d. sans devoir la comparer avec les autres répliques. Contrairement aux travaux existants, par exemple [KWR05], UMS n'a pas besoin de rechercher toutes les répliques pour trouver une réplique courante. En outre, les mises-à-jour concurrentes ne posent aucun problème pour UMS. Nous avons également proposé le service KTS qui produit des estampilles monotonement croissantes, de façon distribuée en utilisant les compteurs locaux. Nous avons validé UMS et KTS par une combinaison d'implémentation avec la DHT Chord sur un cluster de Grid5000 et simulation. Les résultats ont montré l'efficacité de ces deux services.

Nos techniques de réplication en P2P ont été conçues dans le contexte du projet APPA [AMPV04, AMPV06a] qui fournit des services avancés de gestion de données dans les systèmes P2P. Dans le prolongement de nos travaux en réplication, nous poursuivons trois directions de recherche nouvelles dans APPA : un service de réconciliation basé sur des estampilles distribuées continues, un service de gestion de cache, et un service de gestion de flux en P2P.

Réconciliation P2P
Nous proposons une solution nouvelle à la réconciliation en P2P pour l'édition collaborative (dans le cadre du projet Xwiki Concerto). Elle combine l’approche à base de transformées opérationnelles (OT) [SCF98, FVC04, MOSI03] qui permet de réaliser la réconciliation de façon très efficace et simple, et un nouveau service appelé P2P-LTR (Logging and Timestamping for Reconciliation). P2P-LTR réalise la journalisation des actions en P2P et intègre un service d’estampillage continu inspiré de KTS et un algorithme pour retrouver l’ordre total des actions stockées dans le journal P2P. Un défi est la gestion d’estampilles continues qui doit être tolérante aux fautes, afin d’ordonnancer les actions (les modifications sur les documents) stockées dans les journaux.

Gestion de Cache en P2P
Bien que largement déployés pour le partage de fichiers, les systèmes P2P non structurés surexploient les ressources réseaux. Le trafic P2P monopolise la bande passante, notamment à cause de l’inefficacité des mécanismes de recherche aveugle qui inondent le réseau de messages redondants.

Puisque les requêtes dans ces systèmes exhibent une forte localité temporelle, les techniques de mise en cache des réponses de requêtes (c.-à-d. la localité des fichiers) pourraient optimiser la recherche et limiter le trafic redondant. En revanche, la gestion de caches constitue un défi majeur pour éviter le surcoût de stockage. De plus, la majorité des approches existantes ne
prennent pas en compte la proximité réseau entre le client et le fournisseur du fichier, alors que les fichiers populaires sont naturellement répliqués en différentes localités. Ce problème contribue également à la surcharge du réseau et à la dégradation des temps de réponse. Nous proposons d’étudier des techniques de recherche qui profitent de la mise en cache des réponses des requêtes. L’idée est d’exploiter la réplication désordonnée de fichiers en considérant leur localité, pour limiter la consommation de bande passante dans les systèmes P2P non structurés.

Nous nous intéressons aussi à gestion de cache web en P2P. Plusieurs travaux sur les caches web comme Akamai redistribuent le contenu des serveurs web pour un public plus large. Ces techniques absorbent la surcharge des serveurs webs, limitent les coûts de bande passante et optimisent le temps de latence perçus par les clients. Cependant, ces services sont coûteux en termes de maintenance et d’administration. La technologie pair-à-pair est une nouvelle alternative pour redistribuer le contenu à une grande échelle et à bas coûts, tout en exploitant les ressources non utilisées des clients. Plusieurs défis se présentent lors de la conception d’un système de cache web P2P avec des performances comparables à celles des techniques traditionnelles, alors que l’on compte essentiellement sur des nœuds autonomes et dynamiques.

Plus précisément, nous abordons les questions suivantes : quelles données doivent être mises en cache, sur quels nœuds placer le cache, comment gérer les mises-à-jour (et assurer la cohérence des données répliquées), et comment traiter efficacement le routage de requêtes en exploitant le système de caches distribués.

**Gestion de Flux de Données en P2P**

Des applications modernes comme la surveillance de réseau, l’analyse financière ou les réseaux de capteurs requièrent des requêtes continues pour traiter des flux de données (*data streams*). La gestion des flux de tuples produits en continu et de taille non bornée est un domaine de recherche important. La nature continue et non bornée des données a pour conséquence qu’il n’est pas possible de stocker les données sur disque. De plus, cela empêche l’application des optimisations développées sur les opérateurs traditionnels de gestion de données. Il n’est donc pas concevable de traiter les données avec une approche classique.

D’autre part, le succès des applications P2P et ses protocoles a motivé d’aller au-delà des applications de partage de fichiers. C’est ainsi que le paradigme P2P s’est récemment imposé comme la clé du passage à l’échelle dans les systèmes distribués. Dans cette direction, nous intéressons à la conception et l’implémentation d’algorithmes efficaces pour le traitement de requêtes sur des flux de données reposant sur le paradigme P2P.
1 Introduction

In this chapter, we present the main structure and goals of this research work on lazy data replication in different contexts: small, large and very large scale systems. We first introduce the main concepts, relevant terms and some related work. Then we present the context of our research which includes the projects we have been involved. Finally, we present the report organization.

1.1 Data Replication

Data replication is important in the context of distributed systems for several reasons [SS05]. First, replication improves system availability by removing single points of failures (objects are accessible from multiple nodes). Second, it enhances system performance by reducing the communication overhead (objects can be located closer to their access points) and increasing the system throughput (multiple nodes serve the same object simultaneously). Finally, replication improves system scalability as it supports the growth of the system with acceptable response times.

Data replication consists of managing reads and writes over multiple copies of a single object, called replicas, stored in set of interconnected nodes. An object is the minimal unit of replication in a system. For instance, in a replicated relational database, if tables are entirely replicated then tables correspond to objects; however, if it is possible to replicate individual tuples, then tuples correspond to objects. Other examples of objects include XML documents, typed files, multimedia files, etc.

A major issue concerning data replication is how to manage updates. Gray et al. [GHOS96] classify the replica control mechanisms according to two parameters: where updates take place (i.e. which replicas can be updated), and when updates are propagated to all replicas. According to the first parameter (i.e. where), replication protocols can be classified as single-master or multi-master solutions. With single master replication, updates on a replicated object are performed at a single master node, which holds the primary copy (read/write) of the replicated object. Slave nodes, holds secondary copies (read only) of the replicated object. With multi-master replication, all involved nodes holds primary copies of replicated objects. According to the second parameter (i.e. when), update propagation strategies are divided into synchronous and asynchronous approaches. More specifically, in distributed database systems, data access is done via transactions. A transaction is a sequence of read and write operations followed by a commit. If the transaction does not complete successfully, we say that it aborts. The updates of a transaction that updates a replicated object must be propagated to all nodes that hold replicas of this object in order to keep these replicas consistent. Such update propagation can be done
within the transaction boundaries or after the transaction commit. The former is called *synchronous* (henceforth eager) replication, and the latter, *asynchronous* (hence forth lazy) replication.

The replica control solutions are also affected by the way replicas are distributed over the network. Replica placement over the network directly affects the replica control mechanisms. We discuss the basic alternative approaches for replica placement: full replication and partial replication.

*Full replication* consists of storing a copy of every replica of an object at all participating nodes. This approach provides simple load balancing since all nodes have the same capacities, and maximal availability as any node can replace any other node in case of failure. Figure 1.1 presents the full replication of two objects $R$ and $S$ over three nodes.

With *partial replication*, each node may hold a subset of replicated copies, so that the objects replicated at one node may be different of the objects replicated at another node, as shown in Figure 1.2. This approach incurs less storage space and reduces the number of messages needed to update replicas since updates are only propagated towards some nodes. Thus, updates produce less load for the network and nodes. However, if related objects are stored at different nodes, the propagation protocol becomes more complex as the replica placement must be taken into account. In addition, this approach limits load balance possibilities since certain nodes are not able to execute a particular set of transactions.

One of the crucial problems of data replication is updating a replica. The *eager* replication approaches apply updates to all replicas within the context of the transaction that initiates the updates, as shown in Figure 1.3. As a result, when the transaction commits, all replicas have the same state and *mutual consistency* is assured. This is achieved by using concurrency control mechanisms like distributed two-phase-locking (D-2PL) [OV99] or timestamp based algorithms. In addition, a commitment protocol like two-phase-commit (2PC) can be used to provide atomicity (either all transaction’s operations are completed or none of them are). Thus,
eager replication enforces mutual consistency among replicas. Bernstein et al. [BHG87] define this consistency criteria as *one-copy-serializability*, i.e. despite the existence of multiple copies, an object appears as one logical copy (*one-copy-equivalence*), and a set of accesses to the object on multiple nodes is equivalent to serially execute these accesses on a single node.

![Figure 1.3. Principle of lazy replication](image)

Early solutions [Sto79] use synchronous single-master approaches to assure one-copy-serializability. However, later solutions avoid this centralized solution and follow the multi-master approach. For instance, in the ROWA (*read-one/write-all*) approach [BHG87], read operations are done locally while write operations access all copies. ROWA is not fault-tolerant since the update processing stops whenever a copy is not accessible. ROWAA (*read-one/write-all-available*) [BG84,GSC+83] overcomes this limitation by updating only the available copies. Another alternative are quorum protocols [Gil79, JM87, PL88, Tho79], which can succeed as long as a quorum of copies agrees on executing the operation. Other solutions combine ROWA/ROWAA with quorum protocols [ET89].

More recently, Kemme and Alonso [KAA00] proposed new protocols for eager replication that take advantage of group communication systems to avoid some performance limitations introduced by the standard eager solutions when using D-2PL and 2PC. Group communication systems [CKV01] provide group maintenance, reliable message exchange, and message ordering primitives between groups of nodes. The basic mechanism behind these protocols is to first perform a transaction locally, deferring and batching writes to remote replicas until transaction commit time. At commit time all updates (called the write set) are sent to all replicas using a total order multicast primitive which guarantees that all nodes receive all write sets in exactly the same order. As a result, no two-phase commit protocol is needed and no deadlock can occur. Following this approach, Jiménez-Peris et al. [JPAK03] show that the ROWAA approach, instead of quorums, is the best choice for a large range of applications requiring data replication in cluster environments. Next, in [LKPJ05] the most crucial bottlenecks of the existing protocols are identified, and optimizations are proposed to alleviate these problems, making *one-copy-serializability* feasible in wide-area-networks (WAN) environments of
medium size. Finally, [LKPJ07] proposes a replication solution adapted to edge computing which provides higher scalability without the use of group communication at the WAN.

The main advantage of eager replication is to provide mutual consistency within transaction management. This enables local queries to read consistent values. The drawback is that the transaction has to update all replicas before committing, thus increasing transaction response times, with limited scalability (up to ten nodes). In addition, in the presence of failures these protocols may block. The use of group communication improves these limitations somewhat. A group communication system enables a node to multicast a message to all nodes of a group with a delivery guarantee, i.e. the message is eventually delivered to all nodes. Furthermore, it can provide multicast primitives with different delivery orders. In total order multicast, all messages sent by different nodes are delivered in the same total order at all nodes. In eager replication, this primitive was proposed [KA00a] to be used to guarantee that all nodes receive the write operations in exactly the same order, thereby ensuring identical serialization order at each node. In fact, the combination of the use reliable delivery (if one node receives the message all nodes receive the message unless they fail) and total order guarantees atomicity.

With lazy replication, a transaction commits as soon as possible at the master node, and afterwards the updates are propagated towards all other replicas, as shown in Figure 1.4, and replicas are then updated in a separate transactions. As a consequence mutual consistency is relaxed. The concept of freshness is used to measure the deviation between replicas (primary copies and secondary copies) when using lazy single master replication.

Multi-master lazy replication (update anywhere) solutions can be classified as optimistic or non-optimistic according to their way of handling conflicting updates. In general, optimistic replication relies on the optimistic assumption that conflicting updates will occur only rarely, if at all. Tentative updates are applied locally, and later on conflicts are detected and resolved by some reconciliation engine [SS05]. As a result tentative updates may be aborted if necessary, and eventually mutual consistency is assured. Between two reconciliations, inconsistent states are allowed to be read by queries.

In contrast, non-optimistic replication assumes that update conflicts are likely to occur and implements propagation mechanisms that prevent conflicting by establishing some transaction execution strategy, in the fly, to assure total order. These protocols are said to assure strong consistency since an inconsistent state is never seen by queries. However, unfresh states are allowed to be read. This is why strong consistency is different from mutual consistency.
An advantage of lazy propagation is that the replica protocol does not block transaction processing due to unavailable replicas, which improves system liveness in the presence of failures and dynamicity. In addition, less communication overhead is needed to coordinate concurrent updates, thereby reducing the transaction response times and improving the system scalability. In particular, optimistic lazy replication is more flexible than other approaches as the application can choose the appropriate time to perform reconciliation. Thus, applications may progress even over a dynamic network, in which nodes can connect and disconnect at any time. The main drawback is that replicas may be inconsistent or unfresh in the presence of queries, which in some cases may be unacceptable. Non-optimistic lazy replication is not as flexible as the optimistic approach, but completely avoids inconsistent reads, even if unfresh reads are accepted.

1.2 Contributions

In this report, we present our contributions to improve data freshness and to manage strong consistency in single master and multi-master lazy replication configurations, respecting the autonomy of the database internals. This means that all the components necessary to support our protocols are implemented outside de DBMS. These contributions were motivated by distributed database system applications such as small scale Oneline Analysis Processing (OLAP) and small and large scale Oneline Transaction Processing (OLTP) in database cluster system. The motivations of these applications are given in chapters 2 and 3, respectively.

Let us now motivate the needs for replication in peer to peer (P2P) systems since it’s a recent research challenge. Large-scale distributed collaborative applications are getting common as a result of rapid progress in distributed technologies (grid, P2P, and mobile computing). As an example of such applications, consider a second generation Wiki [Wik07] that works over a peer-to-peer (P2P) network and supports users on the elaboration and maintenance of shared documents in a collaborative and lazy manner.
P2P systems adopt a completely decentralized approach to resource management [SMKK+01,RFHK+01,RD01,Gnu06,Kaz06]. By distributing data storage, processing, and bandwidth across autonomous peers in the network, they can scale without the need for powerful servers. All P2P systems rely on a P2P network to operate. This network is built on top of the physical network (typically the Internet), and therefore is referred to as an overlay network. The degree of centralization and the topology of the overlay network tightly affect the properties of the P2P system, such as fault-tolerance, self-maintainability, performance, scalability, and security. For simplicity, we consider three main classes: unstructured, structured, and super-peer networks.

P2P systems allow decentralized data sharing by distributing data storage across all peers of a P2P network. Since these peers can join and leave the system at any time, the shared data may become unavailable. To cope with this problem, a solution is to replicate data over the P2P network. Several data replication solutions have been proposed in P2P systems to improve availability within the overlay network [CMHS+02,ACDD+03, KBCC+00,AHA03]. Most of these solutions are based on lazy single master replication built for file systems. On the other hand, very few replication solutions have been proposed to handle the application requirements.

Our research contributions for managing lazy multi-master data replication in P2P systems are related to specific collaborative applications. We adopt optimistic replication due to its flexibility which is necessary in dynamic and large scale environments. The first contribution in this subject is a P2P Topology Aware Semantic Reconciliation engine. Another important contribution is related to the improvement of performance on providing data availability in structured P2P systems in the presence of multiple replicas of a given object, given dynamicity and failures. In this context, we proposed a data replication service that uses the concept of currency over a distributed timestamp protocol.

To conclude this section, we present a summary of the different contexts of our research on replication:

**Distributed OLTP and OLAP (1999 to 2001) [PMS99, PS00, PMS01]:**

- Mainly Lazy Single Master configurations
- Small scale
- Partial Replication
- Database heterogeneity
- Strong Consistency
Database Clusters (2002 to 2006) [POC03, CGPV04, PCVO05,CPV05a, CPV05b]:

- Lazy Multi-Master and Single Master configurations
- Large scale
- Full and Partial Replication
- Database heterogeneity
- Strong Consistency

P2P Data Management Systems (2003 until today) [AMPV04, MAPV06, MP06, EMP07, APV07a]:

- Lazy Single Master and Multi-Master Replication
- Dynamicity, high heterogeneity (DB, network, peers)
- Large scale or very large scale
- Full and Partial Replication
- Eventual consistency

Besides data replication, we also have important contributions on query processing in distributed P2P systems [AMPV06b, APV07b, APV07] but they are beyond the scope of this report.

1.3 Research Projects

Our research on data replication is motivated by several important research projects presented below:

- ESPRIT Long Term Research (DWQ) Data Warehouse Quality. I worked on DWQ as a Ph.D. student in the Rodin team at Inria Rocquencourt and afterwards, as a research collaborator in the Caravel team at Inria Rocquencourt. Our contribution was the development of algorithms to improve data freshness and managing consistency in lazy single master replication configurations for small scale heterogeneous distributed and replicated database systems.

- RNTL Leg@net (Legacy applications on the Net). I worked on Leg@net first at University of Paris 5 and continued as assistant professor at University of Nantes, in the ATLAS team, a joint team between INRIA and LINA. I supervised the Ph.D. thesis of Cedric Coulon and 3 master theses. Our contribution was the development of lazy muti-master non-optimistic
replication algorithms and architectures for large scale database clusters for OLTP applications. We developed a significant research prototype which was released as open software (RepDB*).

- STREP Grid4All and RNTL XWiki Concerto, as an associated professor at University of Nantes and member the ATLAS team. I supervised the Ph.D. theses of Vidal Martins and Reza Arkbarinia and 4 master theses. I am still working on these projects and supervising 2 engineers for prototyping our solutions. A significant research prototype, Atlas P2P Architecture (APPA) is being developed and incorporates the results of our work. Our contributions are P2P data replication solutions and architectures for lazy multi-master replication for collaborative applications over P2P systems.

1.4 Research Prototypes

The main results of my research have been the basis for the major research prototypes:

**RepDB*: 2002-2005**

We have initially designed it in the context of the Leg@net RNTL project and further developed it in the context of the ARA Masses de données MDP2P project. RepDB* supports preventive data replication capabilities (multi-master modes, partial replication, strong consistency) which are independent of the underlying DBMS. It employs general, non intrusive techniques. It is implemented in Java on Linux and supports various DBMS: Oracle, PostgreSQL and BerkeleyDB. We validated RepDB* on the Atlas 8-node cluster at LINA and another 64-node cluster at INRIA-Rennes. In 2004, we registered RepDB* to the APP (Agence pour la Protection des Programmes) and released it as Open Source Software under the GPL licence. Since then, RepDB* has been available for downloading (with more than a thousand downloads in the first three months).

**Atlas Peer-to-Peer Architecture (APPA): 2006-now**

APPA is a P2P data management system that provides scalability, availability and performance for applications which deal with semantically rich data (XML, relational, etc.).
APPAn provides advanced services such as queries, replication and load balancing. It is being implemented on top of various P2P networks such as JXTA and OpenChord and tested on GRID5000. Three services related to data replication have been implemented so far: KTS, P2P-Reconciler, and P2P-LTR. KTS (Key-based Timestamp Service) is a distributed service to manage timestamps in DHTs (distributerd hash tables). It is useful to solve various DHT problems which need a total order on operations performed on each data, e.g. data currency. P2P-Reconciler is a P2P semantic optimistic reconciliation engine useful for managing multi-master replication for P2P collaborative applications. We are currently developing another service P2P Log and Timestamper for Reconciliation (P2P-LTR) in the Strep Grid4All and RNTL Xwiki Concerto projects as the basis to perform reconciliation of replicated documents in a P2P wiki system.

1.5 Report Organisation

This document is organized as follows. Chapter 2, summarizes and discusses the main contributions related to lazy master replication in the context of OLAP and OLTP applications. Next, in Chapter 3, we present our contributions on lazy multi-master replication for OLTP applications in database clusters. Chapter 4 presents our contributions on Topology Aware Semantic P2P Reconciliation and Chapter 5 presents our contributions on data availability in structured P2P systems. Finally, Chapter 6 concludes and discusses our current and future work. In addition to the 6 chapters that resumes our research work, we also present four annexes. Each annex corresponds to a published paper related to a specific Chapter: Annex A and B (Chapter 2), Annex C (Chapter 3), Annex D (chapter 4) and Annex E (Chapter 5), and details the contributions of these chapters.
2 Lazy Single Master Replication in Data Warehouses

In this chapter, we first present the main applications that motivated our research on lazy single master replication. Next, we summarize: (i) the proposed framework for lazy replication, (ii) two update propagation strategies to improve data freshness based on immediate propagation, (iii) consistency criteria’s in terms of group communication protocols for some important configurations used in OLAP and OLTP (iv) the refresher algorithms used to enforce consistency for acyclic configurations. Next, we compare the contributions with relevant related work. Finally we conclude the section.

2.1 Motivations

Over years companies have built operational database to support their day-to-day operations with On-Line Transaction Processing (OLTP) applications which are transactions oriented (airline reservation, banking, etc). They need extensive data control and availability, high multi-user throughput and predicable, fast response times. The users are clerical. Operational databases are medium to large (up to several gigabytes). In effect, distributed databases have been used to provide integrated access to multiple operational databases and data replication is used to improve response time and availability. To improve response times and scalability up to ten nodes in the internet, lazy single master replication is proposed as an alternative solution to the early eager replication solution. The concept of freshness is then necessary to measure the deviation of primary and secondary copies. In addition, in partial lazy single master replication, consistency management is necessary to express in which order transactions that update replicated data must be executed to avoid inconsistent reads.

Decision support applications have been termed On-Line Analytical Processing (OLAP) [Cod95] to better reflect their different requirements. OLAP applications, such as trend analysis or forecasting, need to analyze historical, summarized data coming from operational databases. They use complex queries over potentially very large tables and read intensive. Because of their strategic nature, response time is important. Performing OLAP queries directly over distributed operational databases raises two problems. First, is hurts the OLTP application performance by competing for local sources. Second, the overall response time of the OLAP queries can be very poor because large quantities of data need to be transferred over the network. Furthermore, most OLAP applications do not need the most current versions of the data and thus do not need direct access to operational data. Data warehousing is the solution to this problem, which extracts and summarizes data from operational data bases in a separate database, dedicated to OLAP. Data warehousing is often considered an alternative to distributed databases, but in fact these are complementary technologies. Lazy single master data replication is used to built distributed data
warehouse and needs high degree of fresh data to improve OLAP analysis quality. In addition, several distributed data warehousing architectures have been proposed and again, consistency management is necessary to express in which order transactions that update replicated data must be executed to avoid inconsistent reads.

2.2 Lazy Single Master Context

With lazy single master replication, updates are performed on a primary copy are first committed at the master node. Afterwards, each secondary copy is updated, in a separate transactions, called refresh transaction. Primary copied are updatable and secondary copies are read-only. In addition, there is a single primary copy for each secondary copy. Lazy single master replication have been widely implemented by current database systems [GHOS96, Lad90]. When we started on this topic, several manuals, documents and few papers provided informal definitions which were general and not precise enough to address the problems related to the applications that motivated our research. To express our contributions, we proposed a formal framework for lazy single master replication based in five basic parameters: ownership, configuration, transaction model, propagation and refreshment. Even though we focused on lazy single master replication, our framework is also valid for lazy multi-master replication. We will use the terms defined in this framework also to compare our work with related ones, later on in this chapter. We pay special attention to the propagation parameter since it expresses important contributions in the field. Finally, we present the way we manage consistency in different lazy single master configurations.

2.3 Basic Parameters

The ownership parameter is inspired from [GHOS96] and defines the nodes capabilities for updating replica copies (primary and secondary copies). Three types of nodes are identified: Master, Slave and MasterSlave. A node is called Master if it stores only primary copies (upper case letter). Similarly, if a nodes store only secondary copies (lower case letter), it is called slave node. Finally, if a node stores primary and secondary copies, it is called MasterSlave.

The configuration parameter defined the components nodes of a replication configuration used in distributed OLTP and data warehousing architectures. We focus on three main configurations: 1Master-nSlaves (Figure 2.1.a), 1Slave-NMaster (Figure 2.1.b), mMaster-nSlave (Figure 2.1.c) and Master-MasterSlave-Slave (Figure 2.1.d).
The transaction model parameter defines the properties of the transactions that access the replica copies at each node. We focus on three types of transactions: update transaction (noted $T$) that update primary copies, refresh transactions (notes $RT$) which carries the sequence of write operations of a specific update transaction used to refresh secondary copies and queries that read secondary copies at the slave nodes.

### 2.4 Propagation and Refreshment

The propagation parameter defines “when” the updates to a primary copy must be multicast towards the nodes storing its secondary copies.

We focus on two types of propagation: deferred and immediate [PSM98]. Deferred propagation is found in commercial database systems and immediate propagation is our proposal. When using deferred propagation strategy, the serial sequence of writes on a set of primary copies performed by an update transaction $T$ is multicast together within a message $M$, after the commitment of $T$. When using an immediate propagation, each write operation performed by a transaction, is immediately multicast inside a message $m$, without waiting for the commitment of the original update transaction $T$.

The refreshment parameter is defined by the triggering and ordering of a refresh transaction at the slave node. The triggering component defines when the delivery (transaction
submission) of a refresh transactions starts with respect to the propagation strategy. Three triggering modes are proposed: deferred, immediate and wait. The couple formed by the propagation and trigger mode determines a specific update propagation strategy. We proposed two update propagation strategies: immediate-immediate and immediate-wait.

With deferred-immediate, as soon as a transaction is committed at the master node the corresponding refresh transaction is multicast towards the slaves nodes and, at the slave node, as soon as RT is received it is submitted to execution. This strategy corresponds to the ones available in some commercial systems.

We proposed the following strategies to improve data freshness since mutual consistency is relaxed. immediate-immediate propagation, involves the sending of each write operation performed by T towards each slave node, without waiting for the commitment of the original update transaction. At the slave node, a refresh transaction is started as soon as the first write operation is received from the master or MasterSlave node. Finally, immediate-wait is similar to immediate-immediate. However, a refresh transaction is submitted for execution only after the complete reception of all write operations of the original update transaction. These immediate strategies allow parallelism between the propagation of updates and the execution of the associated refresh transactions. Figure 2.2 shows these update propagation strategies.

Figure 2.2: Update Propagation Strategies

2.5 Validation of the Update Propagation Strategies

To implement these strategies, we proposed a lazy single master (1Master-nSlave) replication architecture which respects the underlying DBMS heterogeneity and autonomy as a black box. Using this architecture, we simulated these propagation strategies over Oracle 7.3 to measure the gains on data freshness. More formally, given a replica X, which is either a secondary or primary copy, we define n(X,t) as the number of committed update transactions on X at global
time \( t \). It was assumed that update transactions can have different sizes but their occurrence is uniformly distributed over time. Then, the degree of freshness of a secondary copy \( r \) at global time \( t \) is: 
\[
f(r,t) = \frac{n(r,t)}{n(R,t)},
\]
where \( R \) is the primary copy of \( r \). A degree of freshness close to 0 means bad freshness while close to 1 means excellent.

Based on this measure, we studied exhaustively the behaviour of the three update propagation strategies and the results were very good (for complete performance results see Annex A). The results indicate that, for short transactions, the deferred approach performs almost as well as immediate-immediate and immediate-wait. The strategies exhibit different freshness results when long transactions occur. In these cases, the immediate strategies show much better results and the immediate-immediate strategy provides the best freshness results. For some important kinds of workloads, freshness may be five times better than that of the deferred strategy. On the other hand, immediate-wait only improves freshness when the update transaction arrival rate at the master is bursty (i.e. there are short periods (bursts) with high numbers of arriving transactions). The down side of immediate-immediate is the increase of query response times due to transactions blocking when there are conflicts between refresh transactions and queries. However, using a multi-version concurrency control protocol at the slave node, this drawback can be drastically reduced without a significant loss of freshness. The improvement shown by the immediate strategies are beneficial for both OLTP and OLAP applications.

### 2.6 Consistency Management

The consistency parameter enables to express how to achieve refresh transaction total order at the slave nodes with respect to the corresponding update transactions at the master nodes, considering different types of configurations. We express consistency in terms of acceptable group communication primitives. This is an important contribution because it was one of the first approaches to use group communication services [CKV01, Kemm00] together with distributed transaction management for lazy replication. Briefly, group communication systems provide multicast services which may differ in the final order in which message are delivered at each node \( N \) [Kemm00]. Below we present the main services at were useful to define our consistency criteria’s:

1. **Basic service**: A message is delivered whenever it is physically received from the network. Thus, each node receives the message in arbitrary order.
2. **Reliable service**: If a message is delivered in a node then all nodes receive the message unless they fail.

3. **FIFO service**: If a node sends message \( m \) before message \( m' \), then no node receives \( m' \) unless it has previously received \( m \).

4. **Causal order service**: If a message \( m \) causally precedes a message \( m' \) then no node receives \( m' \) until it has previously received \( m \).

5. **Total order service**: All messages are delivered in the same total order at all sites, i.e. if any two nodes \( N \) and \( N' \) receive some messages \( m \) and \( m' \), then either both receive \( m \) before \( m' \) or both receive \( m' \) before \( m \).

Using these services, we express consistency as follow:

- In 1Master-nSlave and nMaster-1Slave configurations, the message delivery order at each slave node must follow the same delivery order that would be obtained when using reliable FIFO multicast service.
- In mMaster-nSlave configuration, the message delivery order at each slave node must follow the same delivery order that would be obtained when using a reliable FIFO Total order multicast service.
- In Master-MasterSlave-Slave configuration, the message delivery order at each slave node must follow the same delivery order that would be obtained when using reliable Causal order multicast service.

### 2.7 Refresher Algorithms

We proposed three Refresher algorithms that assure consistency (for all above configurations) [PMS99, PMS01] (see Annex B), each one related to a specific update propagation strategy. The three algorithms implement refresh transaction ordering in the following way.

It was assumed that the underlying network implements reliable FIFO multicast and has a known upper bound \( \text{Max} \). In addition, it was also assumed that clocks are synchronized, such that the difference between any two clocks is not higher than the precision \( \varepsilon \). All these assumption are acceptable and in the next chapter we relax some of them in the context of database clusters. The timestamp of a message corresponds to the real time value at \( T \)'s commitment time.
To assure consistency for mMaster-nSlave and Master-MasterSlave-Slave configurations, the refresher algorithm works as follows. A refresh transaction RT is committed at a Slave or MasterSlave node (1) once all its write operations have been done, (2) according to the order given by the timestamp $C$ of its associated update transaction, and (3) at the earliest, at real time $C + Max + \varepsilon$. After this delay period, all older refresh transactions are guaranteed to be received at node. Thus total order is assured among update transactions and refresh transaction at all involved slave nodes meeting the consistency requirements.

A key aspect of the refresher algorithm is to rely on the upper bound $Max$ on the transmission of a message by the global FIFO reliable multicast. Therefore, it is essential to have a value $Max$ that is not overestimated. The computation of $Max$ resorts to scheduling theory. Recent work in P2P systems accepts that bounds may be known in relaxed-synchronous systems [BGM04] which is valid for distributed database systems. Thus this assumption is acceptable. The value of $Max$ usually takes into account four kind of parameters. First, there is a global reliable multicast itself. Second, are the characteristics of the message to multicast (e.g. arrival laws, size). For instance in [GM98], an estimation of $Max$ is given for sporadic message arrivals. Third, are the failures to be tolerated by the multicast algorithm (e.g medium access protocol). It is possible to compute an upper bound $Max_i$ for each type $i$ of message to multicast. In that case, the refreshment algorithm at node $N$ waits $max_{i \in J} Max_i$, where $J$ is the set of message types that can be received by node $N$.

Thus, an accurate estimation of $Max$ depends on the accurate knowledge of the above parameters. However, accurate values of the application dependent parameters can be obtained in performance sensitive replicated database applications. For instance, in the case of data warehouse applications that have strong requirements on freshness, certain characteristics of messages can be derived from the characteristics of the operational data sources (usually, transaction processing systems). Furthermore, in a given application, the variations in the transactional workload of the data sources can often be predicted.

There are many alternatives to implement a total order primitive: based on tokens [MMS+96], sequencing [KT96], consensus [CT96], etc. All these solutions require several message rounds [Kem00]. In contrast, for basic FIFO order multicast, a message is simply broadcast to all nodes [CT96,SR96]. Each node tags its message with sequence numbers. Clearly, reliable FIFO multicast is cheaper than the total order service which requires further communication in order to determine the total order.

In summary, the approach taken by the refresher algorithm to enforce total order over an algorithm that implements a global FIFO reliable multicast trades the use of a worst case
multicast time at the benefit of reducing the number of messages exchanged on the network, for instance when using atomic broadcast. This is a well known tradeoff. This solution brings simplicity and ease of implementation.

2.8 Related Work
There are several propagation strategies for lazy single master replication configurations based on push and pull approaches [Dav94, PA99]. Whenever the master node is the one that initiates update propagation then the update propagation strategy follows the push approach. The push approach makes it possible to perform event-driven propagation (implemented by Sybase, Informix and Ingres). In contrast, when the slave requests update propagation, then it follows the pull approach. The drawback of the pull approach is the difficulty to achieve near-real-time update. The main advantage of pull approaches is that it provides scalability, reduces network load by propagating only the last value or aggregated data instead of the whole sequence of updates performed at the master node. Capturing updates on primary copied is done using different capturing mechanisms such as Log Sniffing (ex: Sybase Replication Server) , using triggers (ex: Oracle) to start update propagation, or propagating SQL statements.

Concerning freshness, it has been suggested [ABG90, SR90, AA95, PV98, GNPV07, BFG06] that users should be allowed to specify freshness constraints. The types of freshness constraints that can be specified are the following:

- Time-bound constraints. Users may accept divergence of physical copy values up to a certain time: \( x_i \) may reflect the value of an update at time \( t \) while \( x_j \) may reflect the value at \( t - \Delta \) and this may be acceptable.

- Value bound constraints. It may be acceptable to have values of all physical data items within a certain range of each other. The user may consider the database to be mutually consistent if the values not converge more than a certain amount (or percentage).

- Drift constraints on multiple data items. For transactions that read multiple data items, the users may be satisfied if the time drift between the update timestamps of two data items is less then a threshold.

In [CRR96] the authors proposes a solution that defines a set of allowed configurations using configuration graphs where nodes are sites, and there is non-directed edge between two sites if one has the primary copy and the other a secondary copy for a give data item. In order to provide serializability the resulting configuration must be strongly acyclic. Clearly, this approach does not provide a solution for some important cyclic configurations such as the
Master-MasterSlave-Slave considered in our work. In [BKRS+99], the authors proposed an alternative solution by requiring the directed configuration graph (edges are directed from primary copy to secondary copy) to have no cycles. One strategy transforms the graph into a tree where a primary copy is not necessarily directly connected with all its secondary copies but there exists a path from the primary to each secondary. Update propagation is then performed along the paths of the graph (edges are directed from primary to secondary copy to have no cycles). This also requires to introduce more sophisticated update propagation strategies. Again, no algorithm is provided to refresh secondary copies in the cases of cyclic configurations, such as the Master-MasterSlave-Slave considered in our work.

2.9 Conclusion

In this chapter, we presented our contributions on lazy single master replication [PSM98, PV98, PMS99, PS00, PMS01]. We first addressed the problem related to freshness improvement in lazy single master replicated schemes. More specifically, we dealt with update propagation from primary copy to secondary copies. A complete framework and functional architecture is proposed [PMS01] to define update propagation strategies. We proposed two new strategies called immediate-immediate and immediate-wait, which improve over the deferred strategy of commercial. These strategies allow parallelism between the propagation of updates and the execution of the associated refresh transactions. Immediate-Immediate is the best strategy (by a factor of 5) but may slow down queries. Immediate-wait is almost as good but never slows down queries.

Next, we discussed the contributions related to refreshment algorithms which addresses the central problem of maintaining replicas’ consistency. It delays the execution of a refresh transaction until its deliver time. An observer of a set of replicas at some node never observes a state which is never seen by another observer of the same set of replicas at another node. The basic refresher algorithm may be implemented using the deferred-immediate propagation strategy as well as the immediate strategies to improve freshness in data warehousing applications. Another important contribution is related to the notion of correct refreshment algorithm acceptable for some important configurations in terms of group communication protocols, which is a very important contribution. Annex A and B presents [PS00] and [PMS01] that provides all formalizations and performance evaluation results resumed in this chapter.
3 Lazy Multi-Master Replication in Database Clusters

In this chapter we present preventive replication algorithms used to manage consistency in lazy multi-master replication configurations. This is done in the context of database clusters where scalability is the main concern. We first present the type of applications that motivated this research. Next, as the main contributions of the chapter, we present the type of lazy multi-master configurations we consider and the corresponding preventive replication algorithms necessary to assure consistency with some important optimizations. An important contribution of this work is RepDB* which is an open source software available for downloading. Finally, we compare our approach with important related work and conclude the chapter.

3.1 Introduction

High-performance and high-availability of database management have been traditionally achieved with parallel database systems [Val93], implemented on tightly-coupled multiprocessors. Parallel data processing is then obtained by partitioning and replicating the data across the multiprocessor nodes in order to divide processing. Although quite effective, this solution requires the database system to have full control over the data and is expensive in terms of software and hardware.

Clusters of PC servers now provide a cost-effective alternative to tightly-coupled multiprocessors. They have been used successfully by, for example, Web search engines using high-volume server farms (e.g., Google). However, search engines are typically read-intensive, which makes it easier to exploit parallelism. Cluster systems can make new businesses such as Application Service Providers (ASP) economically viable. In the ASP model, customers’ applications and databases (including data and DBMS) are hosted at the provider site and need to be available, typically through the Internet, as efficiently as if they were local to the customer site. Notice that due to autonomy, it is possible that the DBMS at each node are heterogeneous. To improve performance, applications and data can be replicated at different nodes so that users can be served by any of the nodes depending on the current load [ABKW98]. This arrangement also provides high-availability since, in the event of a node failure, other nodes can still do the work. However, managing data replication in the ASP context is far more difficult than in Web search engines since applications can be update-intensive and both applications and databases must remain autonomous. The solution of using a parallel DBMS is not appropriate as it is expensive, requires heavy migration to the parallel DBMS and hurts database autonomy.

We consider a database cluster with similar nodes, each having one or more processors, main memory (RAM) and disk. Similar to multiprocessors, various cluster system architectures are possible: shared-disk, shared-cache and shared-nothing [Val93]. Shared-disk and shared-cache require a special interconnect that provides a shared space to all nodes with provision for cache coherence using either hardware or software. Shared-nothing (or distributed memory) is the only architecture that supports our autonomy requirements without the additional cost of a special interconnect. Furthermore, shared-nothing can scale up to very large configurations. Thus, we strive to exploit a shared-nothing architecture.
To improve performance in a database cluster, an effective solution is to replicate databases at different nodes so that users can be served by any of them depending on the current load [GNPV92, GNPV07]. This arrangement also provides high-availability since, in the event of a node failure, other nodes can still do the work. However, the major problem of data replication is to manage the consistency of the replicas in the presence of updates [GHOS96]. The basic solution in distributed systems that enforces strong replica consistency is synchronous (or eager) replication (typically using the Read-One-Write All – ROWA protocol [OV99]). Whenever a transaction updates a replica, all other replicas are updated inside the same distributed transaction. Therefore, the mutual consistency of the replicas is enforced. However, synchronous replication is not appropriate for a database cluster for two main reasons. First, all the nodes would have to homogeneously implement the ROWA protocol inside their local transaction manager, thus violating DBMS autonomy. Second, the atomic commitment of the distributed transaction typically relies on the two-phase commit (2PC) protocol which is known to be blocking (i.e., does not deal well with nodes’ failures) and has poor scale up.

A better solution that scales up is lazy replication. Lazy replication allows for different replication configurations. A useful configuration is lazy master where there is only one primary copy. Although it relaxes the property of mutual consistency, strong consistency is assured. However, it hurts availability since the failure of the master node prevents the replica to be updated. A more general configuration is (lazy) multi-master where the same primary copy, called a multi-owner copy, may be stored at and updated by different master nodes, called multi-owner nodes. The advantage of multi-master is high-availability and high-performance since replicas can be updated in parallel at different nodes. However, conflicting updates of the same primary copy at different nodes can introduce replica incoherence. In the rest of this chapter, we present our solution to this problem using preventive replication for full and partial [PCVO95, CPV05a, CPVb05] replication configurations.

3.2 Lazy Multi Master Configurations

A primary copy, denoted by \( R \), is stored at a master node where it can be updated while a secondary copy, denoted by \( r_i \), is stored at one or more slave nodes \( i \) in read-only mode. A multi-master copy, denoted by \( R_i \), is a primary copy that may be stored at several multi-master nodes \( i \). Figure 3.1 shows various replication configurations, using two tables \( R \) and \( S \).

Figure 3.1a shows a bowtie (lazy master) configuration where there are only primary copies and secondary copies. This configuration is useful to speed-up the response times of read-only queries through the slave nodes, which do not manage the update transaction load. However, availability is limited since, in the case of a master node failure, its primary copies can no longer be updated.

---

\(^1\) For any two nodes, the same sequence of transactions is executed in the same order.
Figure 3.1 Replication configurations

Figure 3.1.b shows a fully replicated configuration. In this configuration, all nodes manage the update transaction load because whenever $R$ or $S$ is updated at one node, all other copies need be updated asynchronously at the other nodes. Thus, only the read-only query loads are different at each node. Since all the nodes perform all the transactions, load balancing is easy because all the nodes have the same load (when the specification of the nodes is homogeneous) and availability is high because any node can replace any other node in case of failure.

Figure 3.1.c and Figure 3.1.d illustrate partially replicated configurations where all kinds of copies may be stored at any node. For instance, in Figure 3.1.c, node $N_1$ carries the multi-master copy $R_1$ and the primary copy $S$, node $N_2$ carries the multi-master copy $R_2$ and the secondary copy $s_1$, node $N_3$ carries the multi-master copy $R_3$, and node $N_4$ carries the secondary copy $s_2$. Compared with full replication, only some of the nodes are affected by the updates on a multi-master copy (only those that hold common multi-master copies or one of their corresponding secondary copies in a separate step). Therefore, transactions do not have to be multicast to all the nodes. Thus, the nodes and the network are less loaded and the overhead for refreshing replicas is significantly reduced.

With partial replication a transaction $T$ may be composed of a sequence of read and write operations followed by a commit (as produced by the SQL statement in Figure 3.2) that updates multi-master copies. This is more general than in [POC03] where only write operations are considered. We define a refresh transaction (RT) as the sequence of write operations of a transaction $T$ that updates a set of multi-master copies ($R_1, R_2, \ldots, R_n$) at node $N_i$. RT is extracted from the Log History of $N_i$ and propagated only to the nodes that holds secondary copies of $R_1, R_2, \ldots, R_n$. A refreshment algorithm is the algorithm that manages, asynchronously, the updates on a set of multi-master and secondary copies, once one of the multi-master (or primary) copies is updated by $T$ for a given configuration.

Given a transaction $T$ received in the database cluster, there is an origin node chosen by the load balancer that triggers refreshment, and a set of target nodes that carries replicas involved with $T$. For simplicity, the origin node is also considered a target node. For instance, in Figure 3.1.b whenever node $N_i$ receives a transaction that updates $R_i$, then $N_i$ is the origin node and $N_1, N_2, N_3$ and $N_4$ are the target nodes.
To refresh multi-master copies in the case of full replication, it is sufficient to multicast the incoming transactions to all target nodes. But in the case of partial replication, even if a transaction is multicast towards all nodes, it may happen that the nodes are not able to execute it because they do not hold all the replicas necessary to execute $T$ locally. For instance, Figure 3.1.c allows an incoming transaction at node $N_1$, such as the one in Figure 3.2 to read $S$ in order to update $R_1$. This transaction can be entirely executed at $N_1$ (to update $R_1$) and $N_2$ (to update $R_2$). However it cannot be executed at node $N_3$ (to update $R_3$) because $N_3$ does not hold a copy of $S$. Thus, refreshing multi-master copies in the case of partial replication needs to take into account replica placement.

```
UPDATE R1 SET att1=value
WHERE att2 IN
(SELECT att3 FROM S)
COMMIT;
```

**Figure 3.2** Incoming transaction at node $N_1$

### 3.3 Consistency Management

Informally, a correct refreshment algorithm guarantees that any two nodes holding a common set of replicas, $R_1$, $R_2$, …, $R_n$, must always produce the same sequence of updates on $R_1$, $R_2$, …, $R_n$. We provide a criterion that must be satisfied by the refreshment algorithm in order to be correct:

**Multi-Master Full Replication:** For any cluster configuration that meets a multi-master configuration requirement, the refresh algorithm is correct if and only if the algorithm enforces total order for update transaction execution at each node.

**Multi-Master Partial Replication:** For any cluster configuration meets partially replicated configuration requirement, then the refresh algorithm is correct if and only if the algorithm enforces total order for update and refresh transactions execution at each involved node.

### 3.4 Preventive Refresher for Full Replication

The preventive refresher algorithm comes from the one presented for lazy single master configurations. In this section, we briefly recall how it works here for multi-master configurations. For all details (including partial replication configurations) see Annex C that corresponds to [PCVO05].

We assume that the network interface provides reliable FIFO multicast [HT93]. We denote by $Max$, the upper bound of the time needed to multicast a message from a node $i$ to any other node $j$. We also assume that each node has a local clock. For fairness, clocks are assumed to have a drift and to be...
\( \varepsilon \)-synchronized. This means that the difference between any two correct clocks is not higher that \( \varepsilon \) (known as the precision).

Each transaction is associated with a chronological timestamp value \( C \). The principle of the preventive refreshment algorithm is to submit a sequence of transactions in the same chronological order at each node. Before submitting a transaction at node \( i \), we must check whether there is any older transaction en route to node \( i \). To accomplish this, the submission time of a new transaction at node \( i \) is delayed by \( Max + \varepsilon \). Thus the earliest time a transaction is submitted is \( C + Max + \varepsilon \) (henceforth delivery time).

![Figure 3.3 Refreshment Architecture](image-url)

Whenever a transaction \( T_i \) is to be triggered at some node \( i \), node \( i \) multicasts \( T_i \) to all nodes 1, 2, \ldots, \( n \), including itself. This is the main difference compared to the refresher algorithm used to enforce consistency for NMaster-NSlave (bowtie) configurations. Once \( T_i \) is received at some other node \( j \) (\( i \) may be equal to \( j \)), it is placed in the pending queue in FIFO order with respect to the triggering node \( i \). Therefore, at each multi-master node \( i \), there is a set of queues, \( q_1, q_2, \ldots, q_n \), called pending queues, each of which corresponds to a multi-master node and is used by the refreshment algorithm to perform chronological ordering with respect to the delivery times. Figure 3.3 shows part of the components necessary to run our algorithm. The Refresher reads transactions from the top of pending queues and performs chronological ordering with respect to the delivery times. Once a transaction is ordered, the refresher writes it to the running queue in FIFO order, one after the other. Finally, Deliver keeps checking the head of the running queue to start transaction execution, one after the other, in the local DBMS.

### 3.5 Preventive Replication for Partial Configurations

With partial replication, some of the target nodes may not be able to perform a transaction \( T \) because they do not hold all the copies necessary to perform the read set of \( T \) (recall the discussion on Figure 3.2). However the write sequence of \( T \), which corresponds to its refresh transaction, denoted by \( RT \), must be ordered using \( T \)'s timestamp value in order to ensure consistency. So \( T \) is scheduled as usual but not submitted for execution. Instead, the involved target nodes wait for the reception of the corresponding \( RT \). Then, at origin node \( i \), when the commitment of \( T \) is detected (by sniffing the
DBMS’ log), the corresponding RT is produced and node i multicasts RT towards the target nodes. Upon reception of RT at a target node j, the content of T (still waiting) is replaced with the content of incoming RT and T can be executed.

Let us now illustrate the algorithm with an example of execution. In Figure 3.4, we assume a simple configuration with 4 nodes (N1, N2, N3 and N4) and 2 copies (R and S). N1 carries a multi-owner copy of R and a primary copy of S, N2 a multi-owner copy of R, N3 a secondary copy of S, and N4 carries a multi-owner copy of R and a secondary copy of S. The refreshment proceeds in 5 steps. In step 1, N1 (the origin node) receives T from a client which reads S and updates R1. For instance, T can be the resulting read and write sequence produced by the transaction of Figure 3.2. Then, in step 2, N1 multicasts T to the involved target nodes, i.e. N1, N2 and N4. N3 is not concerned with T because it only holds a secondary copy s. In step 3, T can be performed using the refreshment algorithm at N1 and N4. At N2, T is also managed by the Refresher and then put in the running queue. However, T cannot yet be executed at this target node because N2 does not hold S. Thus, the Deliver needs to wait for its corresponding RT in order to apply the update on R (see step 4). In step 4, after the commitment of T at the origin node, the RT is produced and multicast to all involved target nodes. In step 5, N2 receives RT and the Receiver replaces the content of T by the content of RT. The Deliver can then submit RT.

Partial replication may be blocking in case of failures. After the reception of T, some target nodes would be waiting for RT. Thus, if the origin node fails, the target nodes are blocked. However, this drawback can be easily solved by replacing the origin node by an equivalent node, a node that holds all the replicas necessary to execute T. Once the target node detects the failure of the origin node, it can request an equivalent node j to multicast RT given T’s identifier. At node j, RT was already produced in the same way as at the origin node: transaction T is executed and, upon detection of T’s commitment, an RT is produced and stored in a RT log, necessary to handle failure of the origin node. In the worst case where no other node holds all the replicas necessary to execute T, T is globally aborted.
3.6 Optimizations

In a cluster network (which is typically fast and reliable), in most cases messages are naturally chronologically ordered [PS98]. Only a few messages can be received in an order that is different than the sending order. Based on this property, we can improve our algorithm by submitting a transaction to execution as soon as it is received, thus avoiding the delay before submitting transactions. Yet, we still need to guarantee strong consistency. In order to do so, we schedule the commit order of the transactions in such a way that a transaction can be committed only after $Max + \varepsilon$. Recall that to enforce strong consistency, all the transactions must be performed according to their timestamp order. So, a transaction is out-of-order when its timestamp is lower than the timestamps of the transactions already received. Thus, when a transaction $T$ is received out-of-order, all younger transactions must be aborted and re-submitted according to their correct timestamp order with respect to $T$. Therefore, all transactions are committed in their timestamp order.

Thus, in most cases the delay time ($Max + \varepsilon$) is eliminated. Let $t$ be the time to execute transaction $T$. In the previous basic preventive algorithm, the time spent to refresh a multi-master copy, after reception of $T$, is $Max + \varepsilon + t$. Now, a transaction $T$ is ordered while it is executed. So, the time to
refresh a multi-master copy is \( \text{max}[(\text{Max} + \varepsilon), t] \). In most cases, \( t \) is higher than the delay \( \text{Max} + \varepsilon \). Thus, this simple optimization can well improve throughput as we show in our performance study.

**Figure 3.5 Refreshment Architecture**

The average Figure 3.5 shows part of the components necessary to run our algorithm. The *Refresher* reads transactions from the head of *pending queues* and performs chronological ordering with respect to the delivery times. Once a transaction \( T \) is ordered, the Refresher notifies the Deliver that \( T \) is ordered and ready to be committed. Meanwhile, the Deliver keeps checking the head of the running queue to start transaction execution optimistically, one after the other, inside the local *DBMS*. However, to enforce strong consistency the Deliver only commits a transaction when the Refresher has signaled it.

To improve throughput, we introduce concurrent replica refreshment. In the previous section, the Receiver writes transactions directly into the running queue (optimistically), and afterwards the Deliver reads the running queue contents in order to execute the transaction. On the other hand, to assure consistency, the same transactions are written as usually in the pending queues to be ordered by the Refresher. Hence, the Deliver extracts the transactions from the running queue and performs them one by one in serial order. So, if the Receiver fills the running queue faster than the Deliver empties it, and if arrival rate is higher than the average running rate of a transaction (typically in bursty workloads), the response time increases exponentially and performance degrades.
To improve response time in bursty workloads, we propose to trigger transactions concurrently. In our solution, concurrency management is done outside the database to preserve autonomy (different from [POC03]). Using the existing isolation property of database systems, at each node, we can guarantee that each transaction sees a consistent database at all times. To maintain strong consistency at all nodes, we enforce that transactions are committed in the same order in which they are submitted. In addition, we guarantee that transactions are submitted in the order in which they have been written to the running queue. Thus, total order is always enforced.

However, without access to the DBMS concurrency controller (for autonomy reasons), we cannot guarantee that two conflicting concurrent transactions obtain a lock in the same order at two different nodes. Therefore, we do not trigger conflicting transactions concurrently. To detect that two transactions are conflicting, we determine a subset of the database items accessed by the transaction according to the transaction. If the subset of a transaction does not intersect with a subset of another transaction, then the transactions are not conflicting. For example, in the TPC-C benchmark, the transactions’ parameters allow us to define a subset of tuples that could be read or updated by the transaction. If the subset of the transaction cannot be determined, then we consider the transaction to be conflicting with all other transactions. This solution is efficient if most transactions are known, which is true in OLTP environments.

We can now define two new conditions to be verified by the Deliver before triggering and before committing a transaction:

i. Start a transaction iff the transaction is not conflicting with transactions already started (but not committed) and iff no older transaction waits for the commitment of a conflicting transaction to start.

ii. Commit a transaction iff no older transactions are still running.

Figure 3.6 shows examples of concurrent executions of transactions. Figure 3.6.a illustrates a case where the transactions are triggered sequentially, which is equivalent to the case where all the
transactions are conflicting. Figure 3.6.b, Figure 3.6.c and Figure 3.6.d show parallel executions of transaction \( T_1 \), \( T_2 \) and \( T_3 \). In Figure 3.6.b and Figure 3.6.c, transaction \( T_2 \) finishes before \( T_1 \) but waits for commit because \( T_1 \) is still running (this is represented by a dashed line in the figure). In Figure 3.6.b, \( T_1 \), \( T_2 \) and \( T_3 \) are not conflicting, so they can run concurrently. On the other hand, in Figure 3.6.c, \( T_2 \) is conflicting with \( T_3 \), so \( T_3 \) must wait for the end of \( T_2 \) before starting. Finally, in Figure 3.6.d, \( T_1 \) and \( T_2 \) are conflicting, so \( T_2 \) cannot start before the commitment of \( T_1 \) and \( T_3 \) cannot start before \( T_2 \) because transactions must be executed in the order they are in the running queue.

### 3.7 Validation

We implemented our Preventive Replication Manager in our RepDB* prototype [CGPV04, RepDB] on a cluster of 64 nodes (128 processors) on a Grid5000[Gri06]. RepDB* is a data management component for replicating autonomous databases or data sources in a cluster system. RepDB* supports preventive data replication capabilities (multi-master modes, partial replication, strong consistency) which are independent of the underlying DBMS. It employs general, non intrusive techniques. It is implemented in Java on Linux and supports various DBMS: Oracle, PostGreSQL and BerkeleyDB. We validated RepDB* on the Atlas 8-node cluster at LINA and another 64-node cluster at INRIA-Rennes. In 2004, we registered RepDB* to the APP (Agence pour la Protection des Programmes) and released it as Open Source Software under the GPL licence. Since then, RepDB* has been available for downloading (with more than a thousand downloads in the first three months).

In addition, we did an extensive performance validation based on the implementation of Preventive Replication in our RepDB* prototype over a cluster of 64 nodes running PostgreSQL. Our experimental results using the TPC-C benchmark show that our algorithm scales up very well and has linear response time behavior. We also showed the impact of the configuration on transaction response time. With partial replication, there is more inter-transaction parallelism than with full replication because of the nodes being specialized to different tables and thus transaction types. Thus, transaction response time is better with partial replication than with full replication (by about 15%). The speed-up experiment results showed that the increase of the number of nodes can well improve the query throughput. Finally, we showed that, with our optimistic approach, unordered transactions introduce very few aborts (at most 1%) and that the waiting delay for committing transactions is very small (and reaches zero as transaction time increases).

### 3.8 Related Work

Synchronous (eager) replication can provide strong consistency for most configurations including multi-master but its implementation, typically through 2PC, violates system autonomy and does not scale up. In addition, 2PC may block due to network or node failures. The synchronous solution proposed in [KA00b] reduces the number of messages exchanged to commit transactions compared to 2PC. It uses, as we do, group communication services to guarantee that messages are delivered at each
node according to some ordering criteria. However, DBMS autonomy is violated because the implementation must combine concurrency control with group communication primitives. In addition solutions based on total order broadcast is not well suited for large scale replication because as the number of nodes increases the overhead of messages exchanged may dramatically increase to assure total order. The Database State Machine [SPO01, SPM002] supports partial replication for heterogeneous databases and thus does not violate autonomy. However, its synchronous protocol uses two-phase locking that is known for its poor scalability, thus making it inappropriate for database clusters.

Lazy replication typically trades consistency for performance. Early papers provide the user with a way to control inconsistency. A couple of weak consistency models have been constructed that provide correctness criteria weaker than 1-copy-serializability. For instance, Epsilon-serializability [PL91] measures the distance between database objects like the difference in the value or the number of updates applied. The application can therefore specify the amount of inconsistency tolerated by a transaction. N-Ignorance [KB91] is based on quorums. It relaxes the requirement that quorums must intersect in such a way that the inconsistencies introduced by concurrent transactions are bounded. In Mariposa [SAS+96] the frequency of update propagation depends on how much the maintainer of a replica is willing to pay. Also the degree of data freshness in a query is determined by the price a user wants to pay. However, different from preventive replication, these approaches implement the protocols in the database internals, what normally imposes DBMS homogeneity. Besides, making the choice of the right bound of inconsistency is a non-trivial problem and users must have a good understanding of the inconsistency metrics.

A refreshment algorithm that assures correctness for lazy master configurations is proposed in [PMS01]. This work does not consider multi-master and partial replication as we do.

The synchronous replication algorithms proposed in [JPKA02] provides one-copy-serializability for multi-master and partial replication while preserving DBMS autonomy. However, they require that transactions update a fixed primary copy: each type of transaction is associated with one node so a transaction of that type can only be performed at that node. Furthermore, the algorithm uses 2 messages to multicast the transaction, the first is a reliable multicast and the second is a total ordered multicast. The cost of these messages is higher than the single FIFO multicast message we use. However, one advantage of this algorithm is that it avoids redundant work: the transaction is performed at the origin node and the target nodes only apply the write set of the transaction. In our algorithm, all the nodes that hold the resources necessary for the transaction perform it entirely. We could also remove this redundant work to generalize the multicast of refresh transactions for all nodes instead of only for the nodes that do not hold all the necessary replicas. However, the problem is to decide whether it is faster to perform the transaction entirely or to wait for the corresponding write set from the origin node for short transactions. [JPKA02] also proposes similar optimizations that permit
to overlap transaction processing with the time it takes to deliver total order. Finally their experiments do not show scale-up with more than 15 nodes while we go up to 64 in our experiments.

More recent work has focused on snapshot isolation to improve the performance of read-only transactions. The RSI-PC [PA04] algorithm is a primary copy solution which separates update transactions from read-only transactions. Update transactions are always routed to a main replica, whereas read-only transactions are handled by any of the remaining replicas, which act as read-only copies. Postgres-R(SI) [WK05] proposes a smart solution that does not need to declare transactions properties in advance. It uses the replication algorithm of [JPKA02] which must be implemented inside the DBMS. The experiments are limited to at most 10 nodes. SI-Rep [YKPJ05] provides a solution similar to Postgres-R(SI) on top of PostgreSQL which needs the write set of a transaction before its commitment. Write sets can be obtained by either extending the DBMS, thus hurting DBMS autonomy, or using triggers.

3.9 Conclusion

In this chapter, we proposed two algorithms for preventive replication in order to scale up to large cluster configurations [POC03, CGPV04, CPV05a, CPV05b, PCVO05]. The first algorithm supports fully replicated configurations where all the data are replicated on all the nodes, while the second algorithm supports partially replicated configurations, where only a part of the data are replicated. Both algorithms enforce strong consistency. Moreover, we presented two optimizations that improve transaction throughput; the first optimization eliminates optimistically the delay introduced by the preventive replication algorithm while the second optimization introduces concurrency control features outside the DBMS in which non conflicting incoming transactions may execute concurrently.

We did an extensive performance validation based on the implementation of Preventive Replication in our RepDB* prototype over a cluster of 64 nodes running PostgreSQL. Our experimental results using the TPC-C benchmark show that our algorithm scales up very well and has linear response time behavior. The performance gains strongly depend on the types of transactions and of the configuration. Thus, an important conclusion is that the configuration and the placement of the copies should be tuned to selected types of transactions. Annex C presents [PCVO05] to give a complete view of our contributions (formalizations, proofs, performance evaluation, etc).
4 Semantic Reconciliation in P2P Systems

In this chapter we present our contributions on large scale lazy multi-master master optimistic replication in P2P systems. We first present the kind of applications that motivated this research (P2P wiki). To enable the deployment of such applications in P2P networks, it is required a mechanism to deal with data sharing in a dynamic, scalable and available way. We chose the lazy multi-master optimistic approach. Previous work on optimistic replication has mainly concentrated on centralized systems. Centralized approaches are inappropriate for a P2P setting due to their limited availability and vulnerability to failures and partitions from the network. We focus on the design of a reconciliation algorithm to be deployed in large scale cooperative applications, such as P2P Wiki. The main contribution is a distributed reconciliation algorithm designed for P2P networks (P2P-reconciler).

4.1 Introduction

Peer-to-peer (P2P) systems adopt a completely decentralized approach to data sharing and thus can scale to very large amounts of data and users. Popular examples of P2P systems such as Gnutella [Gnu06] and KaZa [Kaz06] have millions of users sharing petabytes of data over the Internet. Initial research on P2P systems has focused on improving the performance of query routing in unstructured systems, such as Gnutella and KaZa, which rely on flooding. This work led to structured solutions based on distributed hash tables (DHT), e.g. CAN [SMKK+01], Chord [SMKK+01], and Pastry [RD01b].

Large-scale distributed collaborative applications are getting common as a result of rapid progress in distributed technologies (grid, P2P, and mobile computing). As an example of such applications, consider a second generation Wiki that works over a peer-to-peer (P2P) network and supports users on the elaboration and maintenance of shared documents in a collaborative and asynchronous manner. Consider also that each document is an XML file possibly linked to other documents. Wiki allows collaboratively managing a single document as well as composed, integrated documents (e.g. an encyclopedia or a knowledge base concerning the use of an open source operating system). Although the number of users that update in parallel a document $d$ is usually small, the size of the collaborative network that holds $d$ in terms of number of nodes may be large. For instance, the document $d$ could belong to the knowledge base of the Mandriva Club, which is maintained by more than 25,000 members [Man07] or it could belong to Wikipedia, a free content encyclopedia maintained by more than 75,000 active contributors [Wik07].

Many users frequently need to access and update information even if they are disconnected from the network, e.g. in an aircraft, a train or another environment that does not provide good network connection. This requires that users hold local replicas of shared documents. Thus, a P2P Wiki requires optimistic multi-master replication to assure data availability at anytime. With this approach, updates made offline or in parallel on different replicas of the same data may cause replica divergence
and conflicts, which should be reconciled. In order to resolve conflicts, the reconciliation solution can take advantage of application semantic to avoid inconsistent edition wrt. to the document contents. This motivated our research in semantic reconciliation. A detailed example of semantic reconciliation for text edition can be found in [MPEJ08].

Optimistic replication is largely used as a solution to provide data availability for these applications. It allows asynchronous updating of replicas such that applications can progress even though some nodes are disconnected or have failed. This enables asynchronous collaboration among users. However, concurrent updates may cause replica divergence and conflicts, which should be reconciled. In most existing solutions [PSM03, SS05] reconciliation is typically performed by a single node (reconciler node) which may introduce bottlenecks. In addition, if the reconciler node fails, the entire replication system may become unavailable.

A theory for semantic reconciliation was set in IceCube [KRSD01, PSM03] to run in a single node. According to this theory, the application semantics can be described by means of constraints between update actions. A constraint is an application invariant, e.g. a parcel constraint establishes the “all-or-nothing” semantics, i.e. either all parcel’s actions execute successfully in any order, or none does. For instance, consider a user that improves the content of a shared document by producing two related actions \(a_1\) and \(a_2\) (e.g. \(a_1\) changes a document paragraph and \(a_2\) changes the corresponding translation); in order to assure the “all-or-nothing” semantics, the application should create a parcel constraint between \(a_1\) and \(a_2\). These actions can conflict with other actions. Therefore, the aim of reconciliation is to take a set of actions with the associated constraints and produce a schedule, i.e. a list of ordered actions that do not violate constraints.

Different from IceCube, we propose a fully distributed approach to perform P2P reconciliation in a distributed hash table (DHT) overlay [DZDKS03]. DHTs typically provide two basic operations [DZDKS03]: \(put(k, data)\) stores a key \(k\) and its associated \(data\) in the DHT using some hash function; \(get(k)\) retrieves the data associated with \(k\) in the DHT.

Variable latencies and bandwidths, typically found in P2P networks, may strongly impact the reconciliation performance once data access times may vary significantly from node to node. Therefore, in order to build a suitable P2P reconciliation solution, communication and topology awareness must be considered.

### 4.2 P2P semantic reconciliation

IceCube describes the application semantics by means of constraints between actions. An action is defined by the application programmer and represents an application-specific operation (e.g. a write operation on a file or document, or a database transaction). A constraint is the formal representation of an application invariant (e.g. an update cannot follow a delete). Constraints are classified as follows:
**User-defined constraint**\(^2\). Users and applications can create user-defined constraints to make their intents explicit. The \(\text{predSucc}(a_1, a_2)\) constraint establishes causal ordering between actions (i.e. action \(a_2\) executes only after \(a_1\) has succeeded); the \(\text{parcel}(a_1, a_2)\) constraint is an atomic (all-or-nothing) grouping (i.e. either \(a_1\) and \(a_2\) execute successfully or none does); the \(\text{alternative}(a_1, a_2)\) constraint provides choice of at most one action (i.e. either \(a_1\) or \(a_2\) is executed, but not both).

**System-defined constraint**\(^3\). It describes a semantic relation between classes of concurrent actions. The \(\text{bestOrder}(a_1, a_2)\) constraint indicates the preference to schedule \(a_1\) before \(a_2\) (e.g. an application for account management usually prefers to schedule credits before debits); the \(\text{mutuallyExclusive}(a_1, a_2)\) constraint states that either \(a_1\) or \(a_2\) can be executed, but not both.

Let us illustrate user- and system-defined constraints with the example that appears in Figure 4.1. In this example, an action is noted \(a_i^n\), where \(n\) indicates the node that has executed the action and \(i\) is the action identifier. \(T\) is a replicated object, in this case, a relational table; \(K\) is the key attribute for \(T\); \(A\) and \(B\) are any two other attributes of \(T\). \(T_1, T_2, T_3\), and \(T\) are replicas of \(T\). And parcel is a user-defined constraint that imposes atomic execution for \(a_3^1\) and \(a_3^2\). Consider that the actions in Figure 4.1 (with the associated constraints) are concurrently produced by nodes \(n_1, n_2\) and \(n_3\), and should be reconciled.

\[
\begin{align*}
\text{a}_1^1: & \text{update } T_1 \text{ set } A=a_1 \text{ where } K=k1 \\
\text{a}_2^1: & \text{update } T_2 \text{ set } A=a_2 \text{ where } K=k1 \\
\text{a}_1^2: & \text{update } T_1 \text{ set } B=b1 \text{ where } K=k1 \\
\text{a}_2^2: & \text{update } T_3 \text{ set } A=a_3 \text{ where } K=k2 \\
\text{Parcel}(a_3^1, a_3^2) &
\end{align*}
\]

**Figure 4.1**. Conflicting actions on \(T\)

In Figure 4.1, actions \(a_1^1\) and \(a_2^1\) try to update a copy of the same data item (i.e. \(T\)'s tuple identified by \(k1\)). The IceCube reconciliation engine realizes this conflict and asks the application for the semantic relationship involving \(a_1^1\) and \(a_2^1\). As a result, the application analyzes the intents of both actions, and, as they are really in conflict (i.e. \(n_1\) and \(n_2\) try to set the same attribute with distinct values), the application produces a \(\text{mutuallyExclusive}(a_1^1, a_2^1)\) system-defined constraint to properly represent this semantic dependency. Notice that from the point of view of the reconciliation engine \(a_1^1\) also conflicts with \(a_3^1\) and \(a_3^2\) (i.e. all these actions try to update a copy of the same data item). However, by analyzing actions' intents, the application realizes that \(a_3^1\) is semantically independent of \(a_1^1\) and \(a_1^2\) as \(a_3^1\) tries to update another attribute (i.e. \(B\)). Therefore, in this case no system-defined constraints are produced. Actions \(a_3^1\) and \(a_3^2\) are involved in a parcel user-defined constraint, so they are semantically related.

The aim of reconciliation is to take a set of actions with the associated constraints and produce a schedule, i.e. a list of ordered actions that do not violate constraints. In order to reduce the schedule

---

\(^2\) User-defined constraint is called log constraint by IceCube. We prefer user-defined to emphasize the user intent.

\(^3\) System-defined constraint is called object constraint by IceCube. We use system-defined to contrast with user intents.
production complexity, the set of actions to be ordered is divided into subsets called clusters. A cluster is a subset of actions related by constraints that can be ordered independently of other clusters. Therefore, the global schedule is composed by the concatenation of clusters’ ordered actions. To order a cluster, IceCube performs iteratively the following operations:

Select the action with the highest merit from the cluster and put it into the schedule. The merit of an action is a value that represents the estimated benefit of putting it into the schedule (the larger the number of actions that can take part in a schedule containing \(a_i\) is, the larger the merit of \(a_i\) will be). If more than one action has the highest merit (different actions may have equal merits), the reconciliation engine selects randomly one of them.

1. Remove the selected action from the cluster.
2. Remove from the cluster the remaining actions that conflict with the selected action.

This iteration ends when the cluster becomes empty. As a result, cluster’s actions are ordered. In fact, several alternative orderings may be produced until finding the best one.

### 4.3 Overview

We assume that P2P-reconciler is used in the context of a virtual community which requires a high level of collaboration and relies on a reasonable number of nodes (typically hundreds or even thousands of interacting users) [WI097]. The P2P network we consider consists of a set of nodes which are organized as a distributed hash table (DHT) [RFHK+01, SMKK+01]. A DHT provides a hash table abstraction over multiple computer nodes. Data placement in the DHT is determined by a hash function which maps data identifiers into nodes. In the remainder of this chapter we assume that the network is reliable and the lookup service of the DHT does not behave incorrectly.

We have structured the P2P reconciliation in 6 distributed steps in order to maximize parallel computing and assure independence between parallel activities. This structure improves reconciliation performance and availability (i.e. if a node fails, the activity it was executing is assigned to another available node).

With P2P-reconciler, data replication proceeds basically as follows. First, nodes execute local actions to update a replica of an object while respecting user-defined constraints. Then, these actions (with the associated constraints) are stored in the DHT based on the object’s identifier. Finally, reconciler nodes retrieve actions and constraints from the DHT and produce the global schedule, by reconciling conflicting actions in 6 distributed steps based on the application semantics. This schedule is locally executed at every node, thereby assuring eventual consistency [SBK04, SS05]. The replicated data is eventually consistent if, when all nodes stop the production of new actions, all nodes will eventually reach the same value in their local replicas.

In this protocol, we distinguish three types of nodes: the replica node, which holds a local replica; the reconciler node, which is a replica node that participates in distributed reconciliation; and the
provider node, which is a node in the DHT that holds data consumed or produced by the reconcilers (e.g. the node that holds the schedule is called schedule provider).

We concentrate the reconciliation work in a subset of nodes (the reconciler nodes) in order to maximize performance. If we do not limit the number of reconcilers, the following problems take place. First, provider nodes and the network as a whole become overloaded due to a large number of messages aiming to access the same subset of DHT data in a very short time interval. Second, nodes with high-latencies and low-bandwidths can waste a lot of time with data transfer, thereby hurting the reconciliation response time. Our strategy does not create improper imbalance in the load of reconciler nodes as reconciliation activities are not processing intensive.

4.4 Reconciliation objects

Data managed by P2P-reconciler during reconciliation are held by reconciliation objects that are stored in the DHT giving the object identifier. To enable the storage and retrieval of reconciliation objects, each reconciliation object has a unique identifier. P2P-reconciler uses the following reconciliation objects:

- **Action log** $R$ (noted $L_R$): it holds all actions that try to update any replica of the object $R$
- **Clusters set** (noted $CS$): recall that a cluster contains a set of actions related by constraints, and can be ordered independently from other clusters when producing the global schedule. All clusters produced during reconciliation are stored in the clusters set reconciliation object.
- **Action summary** (noted $AS$): it captures semantic dependencies among actions, which are described by means of constraints. In addition, the action summary holds relationships between actions and clusters, so that each relationship describes an action membership (an action is a member of one or more clusters).
- **Schedule** (noted $S$): it contains an ordered list of actions, which is composed from the concatenation of clusters’ ordered actions.

Reconciliation objects are guaranteed to be available using known DHT replication solutions [KWR05]. P2P-reconciler’s liveness relies on the DHT liveness.

4.5 P2P-reconciler Distributed Steps

P2P-reconciler executes reconciliation in 6 distributed steps as showed in Figure 4.2. Any connected node can start reconciliation by inviting other available nodes to engage with it. In the 1st step (node allocation), a subset of engaged nodes is allocated to step 2, another subset is allocated to step 3, and so forth until the 6th step (details about node allocation are provided in the next sections). Nodes at step 2 start reconciliation. The outputs produced at each step become the input to the next one. In the following, we describe the activities performed in each step, and we illustrate parallel processing by explaining how these activities could be executed simultaneously by two reconciler nodes, $n_1$ and $n_2$. 
Step 1 – node allocation: a subset of connected replica nodes is selected to proceed as reconciler nodes.

Step 2 – actions grouping: reconcilers take actions from the action log and put actions that try to update common object items into the same group.

Step 3 – clusters creation: reconcilers take action groups from the action log and split them into clusters of semantically dependent conflicting actions; system-defined constraints are created to represent the semantic dependencies detected in this step; these constraints and the action memberships that describe the association between actions and clusters are included in the action summary; clusters produced in this step are stored in the clusters set.

Step 4 – clusters extension: user-defined constraints are not taken into account in clusters creation (e.g. although \( a_3^1 \) and \( a_3^2 \) belong to a parcel, the previous step does not put them into the same cluster, because they do not update a common object item). Thus, in this step, reconcilers extend clusters by adding to them new conflicting actions, according to user-defined constraints. These extensions lead to new relationships between actions and clusters, which are represented by new action memberships; the new memberships are included in the action summary.

Step 5 – clusters integration: clusters extensions lead to cluster overlapping (an overlap occurs when the intersection of two clusters results a non-null set of actions); in this step, reconcilers bring together overlapping clusters. At this point, clusters become mutually-independent, i.e. there are no constraints involving actions of distinct clusters.

Step 6 – clusters ordering: in this step, reconcilers take clusters from the clusters set and order clusters’ actions; the ordered actions associated with each cluster are stored in the schedule reconciliation object (S); the concatenation of all clusters’ ordered actions makes up the global schedule that is executed by all replica nodes.

At every step, the P2P-reconciler algorithm takes advantage of data parallelism, i.e. several nodes perform simultaneously independent activities on a distinct subset of actions (e.g. ordering of different clusters). No centralized criterion is applied to partition actions. Indeed, whenever a set of reconciler nodes requests data from a provider, the provider node naively supplies reconcilers with about the same amount of data (the provider node knows the maximal number of reconcilers because it receives this information from the node that launches reconciliation).
4.5.1 P2P-reconciler at work

We now illustrate the execution of the P2P-reconciler algorithm over a Chord DHT [SMKK+01] network. For simplicity, we consider only its first 3 steps and a few nodes at work. Figure 4.3 shows 8 nodes and their respective roles in the reconciliation protocol. All of them are replica nodes. Reconciliation objects are stored at provider nodes according to the hashed values associated with the reconciliation object identifiers (e.g. Chord maps a hashed value $v$ to the first node that has an identifier equal to or greater than $v$ in the circle of ordered node identifiers). In this example, we assume that Chord maps the hashed value of the action log identifier to node 1; using the same principle, the clusters set, the schedule and the action summary are mapped respectively to nodes 8, 12 and 15. Finally, node 9 is responsible for allocating reconcilers.

Any node can start the reconciliation by triggering the step 1 of P2P-reconciler at the appropriate node (e.g. node 9), which selects the best reconcilers and notifies them the steps they should perform. In our example, node 9 selects node 2 to execute step 2, and selects nodes 5 and 13 to perform step 3 (details about node allocation are provided in the next sections).

Node 2 starts the step 2 of reconciliation by retrieving actions from the action log (stored at node 1) in order to arrange them in groups of actions on common object items. At the same time, nodes 5 and 13 begin step 3 by requesting action groups to node 1; these requests are held in a queue at node 1 while action groups are under construction. When node 2 stores action groups at action log, node 1 replies the requests previously queued by nodes 5 and 13. At this moment, step 2 is terminated and step 3 proceeds. Notice that each reconciler works on independent data (e.g. nodes 5 and 13 receive distinct action groups from node 1). To assure this independence, provider nodes segment the data they hold based on the number of reconcilers (e.g. node 1 creates two segments of action groups, one for node 5 and another for node 13).

When step 2 terminates, nodes 5 and 13 receive action groups from node 1 and produce the corresponding clusters of actions, which are stored at node 8. In turn, node 8 replies requests for clusters that reconcilers of step 4 have previously queued; and so forth, until the end of step 6.
4.6 Dealing with dynamism

Whenever distributed reconciliation takes place, a set of nodes $N_d$ may be disconnected. As a result, the global schedule is not applied by the nodes of $N_d$. Moreover, actions produced by $N_d$ nodes and not yet stored in the P2P network are not reconciled. We need a new reconciliation object to assure eventual consistency in the presence of disconnections. Thus, we define schedule history, noted $H$, as a reconciliation object that stores a chronological sequence of schedules’ identifiers produced by reconciliations ($H = \{S_{id1}, \ldots, S_{idn}\}$). A replica node can check whether it is up to date by comparing the identifier of the last schedule it has locally executed with $S_{idv}$. Fault-tolerance aspects relies on the DHT, that normally achieved by replicating each peer data at its neighbor.

4.7 DHT cost model

A DHT network is usually built on top of the Internet, which consists of nodes with variable latencies and bandwidths. As a result, the network costs involved in DHT data accesses may vary significantly from node to node and have a strong impact in the reconciliation performance. Thus, network costs should be considered to perform reconciliation efficiently. We propose a basic cost model for computing communication costs in DHTs based on look-up, direct-cost and transfer costs. The look-up cost, noted $lc(n, id)$, is the latency time spent in a lookup operation launched by node $n$ to find the data item identified by $id$. Similarly, direct cost, noted $dc(n_i, n_j)$, is the latency time spent by node $n_i$ to directly access $n_j$. And the transfer cost, noted $tc(n_i, n_j, d)$, is the time spent to transfer the data item $d$ from node $n_i$ to node $n_j$, which is computed based on $d$’s size and the bandwidth between $n_i$ and $n_j$. On top of it, we can build customized cost models.

In the basic cost model, we define communication costs (henceforth costs) in terms of latency and transfer times, and we assume links with variable latencies and bandwidths. In order to exploit bandwidth, the application behavior in terms of data transfer should be known. Since this behavior is application-specific, we exploit bandwidth in higher-level customized models.

4.8 P2P-reconciler node allocation

The first step of P2P-reconciler aims to select the best nodes to proceed as reconcilers in order to maximize performance. The number of reconcilers has a strong impact on the reconciliation time. Thus, this section concerns the estimation of the optimal number of reconcilers per step as well as the allocation of the best nodes. We first determine the maximal number of reconciler nodes using polynomial regression (for details see [MPV06a]). Then, we use the P2P-reconciler cost model for computing the cost of each reconciliation step. Next, the cost provider node selects reconcilers based on P2P-reconciler cost model. We proposed an approach for managing the dynamic behavior of P2P-reconciler costs.
4.8.1 P2P-reconciler cost model

The P2P-reconciler cost model is built on top of the DHT cost model by taking into account each reconciliation step and defining a new metric: node step cost. The node step cost, noted $\text{cost}(i, n)$, is the sum of lookup (noted $\text{lc}$), direct access (noted $\text{dc}$), and transfer costs (noted $\text{tc}$) estimated by node $n$ for executing step $i$ of P2P-reconciler algorithm.

By analyzing the P2P-reconciler behavior in terms of lookup, direct access, and data transfer operations at every step, we produced a cost formula for each step of P2P-reconciler, which are shown in Table 4.1. There is no formula associated with step 1 because it is not performed by reconciler nodes.

</tr>
</tbody>
</table>

Table 4.1 P2P-reconciler cost model

For instance in formula 2, $\text{lc}(n, LR)$ is the lookup cost from node $n$ to the node that holds $LR$, necessary to locate the provider of $R$. Due to space limitations we do not go further on the cost model discussion. Annex D, that corresponds to [MPEJ08], presents all the precisions on how these formulas are estimated and used.

4.9 Node allocation

Node allocation is the first step of P2P-reconciler protocol as shown in Figure 4.2. It aims to select for every succeeding step a set of reconciler nodes that can perform reconciliation with good performance.

We define a new reconciliation object needed in node allocation. Then we describe how reconciler nodes are chosen, and we illustrate that with an example.

We define communication costs, noted $\text{CC}$, as a reconciliation object that stores the node step costs estimated by every replica node and used to choose reconcilers before starting reconciliation.

The node that holds $\text{CC}$ in the DHT at a given time is called cost provider, and it is responsible for allocating reconcilers. The allocation works as follows. Replica nodes locally estimate the costs for executing every P2P-reconciler step, according to the P2P-reconciler cost model, and provide this information to the cost provider. The node that starts reconciliation computes the maximal number of reconcilers per step ($\text{maxRec}$), and asks the cost provider for allocating at most $\text{maxRec}$ reconciler nodes. Then, the cost provider allocates these reconcilers according to the cost model and provides them with their designated steps.
nodes per P2P-reconciler step. As a result, the cost provider selects the best nodes for each step and notifies these nodes of the P2P-reconciler steps they should execute.

In our solution, the cost management is done in parallel with reconciliation. Moreover, it is network optimized since replica nodes do not send messages to cost providers, informing their estimated costs, if the node step costs overtake the cost limit. For these reasons, the cost provider does not become a bottleneck.

4.9.1 Managing the dynamic costs

The costs estimated by replica nodes for executing P2P-reconciler steps change as a result of disconnections and reconnections. To cope with this dynamic behavior and assure reliable cost estimations, a replica node $n_i$ works as follows:

**Initialization**: whenever $n_i$ joins the system, $n_i$ estimates its costs for executing every P2P-reconciler step. If these costs do not overtake the cost limit, $n_i$ supplies the cost provider with this information.

**Refreshment**: while $n_i$ is connected, the join or leave of another node $n_j$ may invalidate $n_i$’s estimated costs due to routing changes. Thus, if the join or leave of $n_j$ is relevant to $n_i$, $n_i$ recomputes its P2P-reconciler estimated costs and refreshes them at the cost provider.

**Termination**: when $n_i$ leaves the system, if its P2P-reconciler estimated costs are smaller than cost limit (i.e. the cost provider holds $n_i$’s estimated costs), $n_i$ notifies its departure to the cost provider.

P2P-reconciler computes the cost limit based on these parameters: the expected average latency of the network (e.g. 150ms for the Internet), and the expected average number of hops to lookup a reconciliation object (e.g. $\log(n)/2$ for a Chord DHT, where $n$ represents the number of connected nodes and can be established as 15% of the community size).

4.10 P2P-reconciler-TA protocol

P2P-reconciler-TA is a distributed protocol for reconciling conflicting updates in topology-aware P2P networks. Given a set of nodes, we exploit topological information to select the “best” nodes to participate in the different steps of an algorithm, in a way that achieves an optimal performance. A P2P network is classified as topology-aware if its topology is established by taking into account the physical distance among nodes (e.g. in terms of latency times).

Several topology-aware P2P networks could be used to validate our approach such as Pastry [RD01a], Tapestry [ZHSR+04], CAN [RFHK+01], etc. We chose to construct our P2P-reconciler-TA over optimized CAN because it allows building the topology-aware overlay network in a relatively simple manner. In addition, its routing mechanism is easy to implement, although less efficient than other topology-aware P2P networks (e.g. the average routing path length in CAN is usually greater than in other structured P2P networks).
Basic CAN [RFHK+01] is a virtual Cartesian coordinate space to store and retrieve data as \((key, value)\) pairs. At any point in time, the entire coordinate space is dynamically partitioned among all nodes in the system, so that each node owns a distinct zone that represents a segment of the entire space. To store (or retrieve) a pair \((k_i, v_i)\), key \(k_i\) is deterministically mapped onto a point \(P\) in the coordinate space using a uniform hash function, and then \((k_i, v_i)\) is stored at the node that owns the zone to which \(P\) belongs. Intuitively, routing in CAN works by following the straight line path through the Cartesian space from source to destination coordinates.

Optimized CAN aims at constructing its logical space in a way that reflects the topology of the underlying network. It assumes the existence of well-known landmarks spread across the network. A node measures its round-trip time to the set of landmarks and orders them by increasing latency (i.e. network distance). The coordinate space is divided into bins such that each possible landmarks ordering is represented by a bin. Physically close nodes are likely to have the same ordering and hence will belong to the same bin.

Briefly, P2P-reconciler-TA works as follows. Based on the network topology, it selects the best provider and reconciler nodes. These nodes then reconcile conflicting updates and produce a schedule, which is an ordered list of non-conflicting updates. We proposed a dynamic distributed algorithm for efficiently selecting provider and reconciler nodes.

### 4.11 Validation

We validated and evaluated the performance of our reconciliation solutions through experimentation using the APPA prototype [AM07]. The validation of the APPA replication service took place over the Grid5000 platform [Gri06]. Grid5000 aims at building a highly reconfigurable, controllable and monitorable experimental Grid platform, gathering 9 sites geographically distributed in France featuring a total of 5000 nodes. Within each site, the nodes are located in the same geographic area and communicate through Gigabit Ethernet links as clusters. Communications between clusters are made through the French academic network (RENATER). Grid5000’s nodes are accessible through the OAR batch scheduler from a central user interface shared by all the users of the Grid. A cross-clusters super-batch system, OARGrid, is currently being deployed and tested. The home directories of the users are mounted with NFS on each of the infrastructure’s clusters. Data can thus be directly accessed inside a cluster. Data transfers between clusters have to be handled by the users. The storage capacity inside each cluster is a couple of hundreds of gigabytes. Now more than 600 nodes are involved in Grid5000. Additionally, in order to study the scalability of the APPA replication service with larger numbers of nodes that are connected by means of links with variable latencies and bandwidths, we implemented simulators using Java and SimJava [HM98], a process based discrete event simulation package. Simulations were executed on an Intel Pentium IV with a 2.6 GHz processor, and 1 GB of main memory, running the Windows XP operating system. The performance results obtained from the simulator are consistent with those of the replication service prototype.
In the implementation intended for the Grid5000 platform, each peer manages multiple tasks in parallel (e.g. routing DHT messages, executing a DSR step, etc.) by using multithreading and other associated mechanisms (e.g. semaphores); in addition, peers communicate with each other by means of sockets and UDP depending on the message type. To have a topology close to real P2P overlay networks in this Grid platform, we determine the peers’ neighbors and we allow that every peer communicate only with its neighbors in the overlay network. Although the Grid5000 provides fast and reliable communication, which usually is not the case for P2P systems, it allows to validate the accuracy of APPA distributed algorithms and to evaluate the scalability of APPA services. We have deployed APPA over this platform because it was the largest network available to perform our experiments in a controllable manner. On the other hand, the implementation of the simulator conforms to the SimJava model with respect to parallel processing and peers communication. It is important to note that, in our simulator, only the P2P network topology and peer communications are simulated; full-fledged APPA services are deployed on top of the simulated network.

The experimental results showed that our cost-based reconciliation outperforms the random approach by a factor of 26. In addition, the number of connected nodes is not important to determine the reconciliation performance due to the DHT scalability and the fact that reconcilers are as close as possible to the reconciliation objects. The action size impacts the reconciliation time in a logarithmic scale. Our algorithm yields high data availability and excellent scalability, with acceptable performance and limited overhead.

In the same way, we also validated P2P-reconciler-TA. The experimental results show that our topology-aware approach achieves a performance improvement of 50% in comparison with the P2P-reconciler. In addition, P2P-reconciler-TA has proved to be scalable with limited overhead and thereby suitable for P2P environments. Our topology-aware approach is conceived for distributed reconciliation; however our metrics, costs functions as well as our selection approach are useful in several contexts.

4.12 Related work

In the context of P2P networks, there has been little work on managing data replication in the presence of updates. Most of data sharing P2P networks consider the data they provide to be very static or even read-only. Freenet [CMHS+02] partially addresses updates which are propagated from the updating peer downward to close peers that are connected. However, peers that are disconnected do not get updated. P-Grid [ACDD0+3, AHA03] is a structured P2P network that exploits epidemic algorithms to address updates. It assumes that conflicts are rare and their resolution is not necessary in general. In addition, P-Grid assumes that probabilistic guarantees instead of strict consistency are sufficient. Moreover, it only considers updates at the file level. In OceanStore [KBCC+00] every update creates a new version of the data object. Consistency is achieved by a two-tiered architecture: a client sends an update to the object’s primary copies and some secondary replicas in parallel. Once the update is
committed, the primary copies multicast the result of the update down the dissemination tree. OceanStore assumes an infrastructure comprised of servers that are connected by high-speed links. Different from the previous works, we propose to distribute the reconciliation engine in order to provide high availability.

Table 4.2 compares the replication solutions provided by different types of P2P systems. Clearly, none of them provide eventual consistency among replicas along with weak network assumptions, which is the main concern of this work.

The distributed log-based reconciliation algorithms proposed by Chong and Hamadi [CH06] addresses most of our requirements, but this solution is unsuitable for P2P systems as it does not take into account the dynamic behavior of peers and network limitations. Operational transformation [VCFS00, MOSI03, FVC04] also addresses eventual consistency among replicas specifically for text edition at the character level with no flexibility wrt. to semantic constraint specification.

Table 4.2 Comparing replication solutions in P2P systems

In the context of APPA (Atlas Peer-to-Peer Architecture), a P2P data management system which we are building [AMPV06b, MAPV06], we proposed the DSR-cluster algorithm [MPJV06, MPV05], a distributed version of the semantic reconciliation engine of IceCube [KRSD01, PSM03] for cluster networks. However, DSR-cluster does not take into account network costs during reconciliation. A fundamental assumption behind DSR-cluster is that the communication costs among cluster nodes are negligible. This assumption is not appropriate for P2P systems, which are usually built on top of the Internet. In this case, network costs may vary significantly from node to node and have a strong impact on the performance of reconciliation.

4.13 Conclusion

Our main contribution related to optimistic lazy multi-master replication is P2P-reconciler, a distributed protocol for semantic reconciliation in P2P networks [MPV05, MPJV06, MAPV06, MP06, AMPV06a, MPV06a, MPV06b, EPV07, MPEJ08]. Other relevant
related contributions are: the cost model for computing communication costs in DHTs and an algorithm that takes into account these costs and the P2P-reconciler steps to select the best reconciler nodes. For computing communication costs, we use local information and we deal with the dynamic behavior of nodes.

Another important contribution is the topology-aware approach to improve response times in P2P distributed semantic reconciliation. The P2P-reconciler-TA algorithm dynamically takes into account the physical network topology combined with the DHT properties when executing reconciliation. We proposed topology-aware metrics and cost functions to be used for dynamically selecting the best nodes to execute reconciliation, while considering dynamic data placement.

We validated P2P-reconciler and P2P-reconciler-TA through implementation and simulation. The experimental results showed that our cost-based reconciliation has very impressive results in scaling up, showing the relevance of our work for P2P collaborative applications. In addition, experimental results show that our topology-aware approach achieves a performance improvement of 50 % in comparison with the P2P-reconciler. In addition, P2P-reconciler-TA has proved to be scalable with limited overhead and thereby suitable for P2P environments. Our topology-aware approach is conceived for distributed reconciliation; however our metrics, costs functions as well as our selection approach are useful in several contexts. Annex D presents [MPEJ08] to give a larger view of our contributions (formalization, detailed algorithms, performance evaluation, etc).
5 Data Currency in Structured P2P Networks

Distributed Hash Tables (DHTs) provide a scalable solution for data sharing in P2P systems. To ensure high data availability, DHTs typically rely on data replication, yet without data currency guarantees. Supporting data currency in replicated DHTs is difficult as it requires the ability to return a current replica despite peers leaving the network or concurrent updates. In this chapter, we describe an Update Management Service (UMS) to deal with data availability and efficient retrieval of current replicas based on timestamping. For generating timestamps, we proposed a Key-based Timestamping Service (KTS) which performs distributed timestamp generation using local counters.

5.1 Introduction

While there are significant implementation differences between DHTs [SMKK+1, SMKK+1, RD01b], they all map a given key $k$ onto a peer $p$ using a hash function and can lookup $p$ efficiently, usually in $O(\log n)$ routing hops where $n$ is the number of peers. DHTs typically provide two basic operations [SMKK+01]: $\text{put}(k, \text{data})$ stores a key $k$ and its associated data in the DHT using some hash function; $\text{get}(k)$ retrieves the data associated with $k$ in the DHT.

One of the main characteristics of P2P systems is the dynamic behavior of peers which can join and leave the system frequently, at anytime. When a peer gets offline, its data becomes unavailable. To improve data availability, most DHTs rely on data replication by storing $(k, \text{data})$ pairs at several peers, e.g. using several hash functions [RFHK+1]. If one peer is unavailable, its data can still be retrieved from the other peers that hold a replica. However, the mutual consistency of the replicas after updates can be compromised as a result of peers leaving the network or concurrent updates. Let us illustrate the problem with a simple update scenario in a typical DHT. Let us assume that the operation $\text{put}(k, d_0)$ (issued by some peer) maps onto peers $p_1$ and $p_2$ which both get to store the data $d_0$. Now consider an update (from the same or another peer) with the operation $\text{put}(k, d_1)$ which also maps onto peers $p_1$ and $p_2$. Assuming that $p_2$ cannot be reached, e.g. because it has left the network, then only $p_1$ gets updated to store $d_1$. When $p_2$ rejoins the network later on, the replicas are not consistent: $p_1$ holds the current state of the data associated with $k$ while $p_2$ holds a stale state. Concurrent updates also cause inconsistency. Consider now two updates $\text{put}(k, d_2)$ and $\text{put}(k, d_3)$ (issued by two different peers) which are sent to $p_1$ and $p_2$ in reverse order, so that $p_1$’s last state is $d_2$ while $p_2$’s last state is $d_3$. Thus, a subsequent $\text{get}(k)$ operation will return either stale or current data depending on which peer is looked up, and there is no way to tell whether it is current or not. For some applications (e.g. agenda management, bulletin boards, cooperative auction management, reservation management, etc.) which could take advantage of a DHT, the ability to get the current data is very important.

Many solutions have been proposed in the context of distributed database systems for managing replica consistency [OV99] but the high numbers and dynamic behavior of peers make them no longer applicable to P2P [KWR05]. Supporting data currency in replicated DHTs requires the ability to return
a current replica despite peers leaving the network or concurrent updates. The problem is partially
addressed in [DGY03] using data versioning. Each replica has a version number which is increased
after each update. To return a current replica, all replicas need to be retrieved in order to select the
latest version. However, because of concurrent updates, it may happen that two different replicas have
the same version number thus making it impossible to decide which one is the current replica. In the
remainder of this chapter we assume that the network is reliable and the lookup service of the DHT
does not behave incorrectly.

In this chapter, we present our solution to data currency in DHT [APV07a] (see Annex E for all
details).

5.2 Data Currency in DHT using UMS and KTS

We provided a complete solution to data availability and data currency in replicated DHTs
[APV07a]. This solution is the basis for a service called Update Management Service (UMS) which
deals with efficient insertion and retrieval of current replicas based on timestamping. Experimental
validation has shown that UMS incurs very little overhead in terms of communication cost. After
retrieving a replica, UMS detects whether it is current or not, i.e. without having to compare with the
other replicas, and returns it as output. Thus, UMS does not need to retrieve all replicas to find a
current one. UMS only requires the DHT’s lookup service with put and get operations.

To provide high data availability, the data is replicated in the DHT using a set of independent hash
functions $H_r$, called replication hash functions. The peer that is responsible for $k$ wrt $h$ at the current
time is denoted by $rsp(k,h)$. To be able to retrieve a current replica, each pair $(k, data)$ is “stamped”
with a logical timestamp, and for each $h \in H_r$, the pair $(k, newData)$ is replicated at $rsp(k,h)$ where
newData=$\{data, timestamp\}$, i.e. newData is a data composed of the initial data and the timestamp.
Upon a request for the data associated with a key, we can thus return one of the replicas which are
stamped with the latest timestamp. The number of replication hash functions, i.e. $|H_r|$, can be
different for different DHTs. For instance, if in a DHT the availability of peers is low, for increasing
data availability a high value of $|H_r|$ (e.g. 30) is used.

To generate timestamps, UMS uses a distributed service called Key-based Timestamping Service
(KTS). The main operation of KTS is $\text{gen}_\text{ts}(k)$ which given a key $k$ generates a real number as a
timestamp for $k$. The timestamps generated by KTS have the monotonicity property, i.e. two
timestamps generated for the same key are monotonically increasing. This property allows ordering
the timestamps generated for the same key according to the time at which they have been generated.
KTS has another operation denoted by $\text{last}_\text{ts}(k)$ which given a key $k$ returns the last timestamp
generated for $k$ by KTS.

At anytime, $\text{gen}_\text{ts}(k)$ generates at most one timestamp for $k$, and different timestamps for $k$ have
the monotonicity property. Thus, in the case of concurrent calls to insert a pair $(k, data)$, i.e. from
different peers, only the one that obtains the latest timestamp will succeed to store its data in the DHT.
Through probabilistic analysis, we compute the expected number of replicas which UMS must retrieve for finding a current replica. Except for the cases where the availability of current replicas is very low, the expected number of retrieved replicas is typically small, e.g. if at least 35% of available replicas are current then the expected number of retrieved replicas is less than 3.

5.3 Validation
We validated our solution through implementation and experimentation over a 64-node cluster of GRID 5000 and evaluated its scalability through simulation over 10,000 peers using SimJava. We compared the performance of UMS and BRK (from the BRICK project [KWR05]) which we used as baseline algorithm. The experimental and simulation results show that using KTS, UMS achieves major performance gains, in terms of response time and communication cost, compared with BRK. The response time and communication cost of UMS grow logarithmically with the number of peers of the DHT. Increasing the number of replicas, which we replicate for each data in the DHT, increases very slightly the response time and communication cost of our algorithm. In addition, even with a high number of peer fails, UMS still works well. In summary, this demonstrates that data currency, a very important requirement for many applications, can now be efficiently supported in replicated DHTs.

The current implementation of our prototype in APPA is based on Open Chord [OCH] which is an open source implementation of the Chord protocol. Open Chord is distributed under the GNU General Public License (GPL). It provides all DHT functionalities which are needed for implementing UMS and KTS, e.g. lookup, get and put functions.

In our prototype, peers are implemented as Java objects. They can be deployed over a single machine or several machines connected together via a network. Each object contains the code which is needed for implementing UMS and KTS. To communicate between peers, we use Java RMI [JRMI] which allows an object to invoke a method on a remote object.

The prototype provides a GUI that enables the user to manage the DHT network (e.g. create the DHT, add/remove peers to/from the system, etc.), store/retrieve data in/from the DHT, monitor the data stored at each peer, the keys for which the peer has generated a timestamp, the set of its initiated counters, etc.

5.4 Related Work
In the context of distributed systems, data replication has been widely studied to improve both performance and availability. Many solutions have been proposed in the context of distributed database systems for managing replica consistency [OV99], in particular, using eager or lazy (multi-master) replication techniques. However, these techniques either do not scale up to large numbers of peers or raise open problems, such as replica reconciliation, to deal with the open and dynamic nature of P2P systems.
Data currency in replicated databases has also been widely studied [BFRG06, GLR05, RBSS02]. However, the main objective is to trade currency and consistency for performance while controlling the level of currency or consistency desired by the user. Our objective in this paper is different, i.e. return the current (most recent) replica as a result of a get request.

Most existing P2P systems support data replication, but without consistency guarantees. For instance, Gnutella [Gnu06] and KaZaA [Kaz06], two of the most popular P2P file sharing systems allow files to be replicated. However, a file update is not propagated to the other replicas. As a result, multiple inconsistent replicas under the same identifier (filename) may co-exist and it depends on the peer that a user contacts whether a current replica is accessed.

PGrid is a structured P2P system that deals with the problem of updates based on a rumor-spreading algorithm. It provides a fully decentralized update scheme, which offers probabilistic guarantees rather than ensuring strict consistency. However, replicas may get inconsistent, e.g. as a result of concurrent updates, and it is up to the users to cope with the problem.

The Freenet P2P system [CMH02] uses a heuristic strategy to route updates to replicas, but does not guarantee data consistency. In Freenet, the query answers are replicated along the path between the peers owning the data and the query originator. In the case of an update (which can only be done by the data’s owner), it is routed to the peers having a replica. However, there is no guarantee that all those peers receive the update, in particular those that are absent at update time.

The BRICKS project [KWR05] deals somehow with data currency by considering the currency of replicas in the query results. For replicating a data, BRICKS stores the data in the DHT using multiple keys, which are correlated to the key $k$ by which the user wants to store the data. There is a function that, given $k$, determines its correlated keys. To deal with the currency of replicas, BRICKS uses versioning. Each replica has a version number which is increased after each update. However, because of concurrent updates, it may happen that two different replicas have the same version number thus making it impossible to decide which one is the current replica. In addition, to return a current replica, all replicas need be retrieved in order to select the latest version. In our solution, concurrent updates raise no problem, i.e. this is a consequence of the monotonicity property of timestamps which are generated by KTS. In addition, our solution does not need to retrieve all replicas, and thus is much more efficient.

5.5 Conclusion

We proposed an Update Management Service (UMS) to deal with data availability and efficient retrieval of current replicas based on timestamping. For generating timestamps, we propose a Key-based Timestamping Service (KTS) which performs distributed timestamp generation using local counters. The validation of UMS-KTS shows excellent in scalability and outperforms significantly the BRICK solution. Annex E presents [APV07a] which provides all details of our contributions (formalizations, detailed algorithms, proofs, performance evaluation, etc).
Several important P2P applications can take advantage of KTS. For instance a reconciliation engine can exploit the use KTS to provide timestamps on tentative actions. This actions may be then reconciled based on the timestamp numbers. This research topic is presented as part of future work.
6 Conclusions and Future Work

6.1 General Conclusions

In this report, we presented our contributions on lazy data replication in different contexts (data warehouse, database clusters, P2P Systems). Since we presented the main related work in each chapter, we now summarize the main lessons learned. We learned that important parameters should be considered when using lazy replication for distributed applications: configuration, scalability, application consistency requirements, database visibility, node dynamicity, node and network load balancing, and network characteristics. These parameters define the relevant requirements for consistency management. Table 6.1 summarizes our research contributions considering all parameters, which we discuss below.

The configuration parameter is related to where replicas can be updated. In a small scale distributed systems, normally lazy single master configurations are sufficient because for the type of application we consider (small scale OLAP and OLTP), the single master is rarely a bottleneck. Furthermore, load balancing is not an issue. This context corresponds to that of Chapter 2. With respect to network characteristics, since nodes are static we can safely employ FIFO reliable multicast without degrading the overall performance. In addition, for clock synchronization we can rely on network time protocols [Mil06]. With respect to consistency management, we expressed total order requirements in terms of group communication primitives. In this context, our solution for managing replica consistency is to improve data freshness by using immediate propagation strategies. To assure total order we proposed a refresher algorithm which delays the execution of refresh transactions until its deliver time. Given our parameter setting, this solution is quite acceptable and simple to implement while respecting database autonomy.

In database clusters, from the user perspective, the system should appear as a single unit. Adaptability plays a crucial role in providing the user with the desired quality of service. Thus, several nodes must have the right to update replicated data to enable the system to adapt to manage load balance and failures. This context corresponds to that of Chapter III. In this context, nodes are static and the network is reliable and fast. Again, we can safely employ FIFO reliable multicast without degrading the overall performance. In addition, for clock synchronization we can rely on network time protocols. Again, with respect to consistency management, we expressed total order requirements in terms of group communication primitives. In this context, our solution for managing replica consistency is to delay the execution of all update and refresh transactions (for partial replication) submitted to the cluster, until its deliver time at a specific node. The optimizations we proposed for preventive replication on submitting updated transactions optimistically yield excellent gains that almost compensate the delay time. In most cases, it eliminates the delay time. In this context, the use
of total order primitives could be an alternative solution to multicast transactions towards all nodes in the cluster. However, the network performance could be degraded in *bursty* workloads, due to the overhead of message exchange, necessary to implement the total order service. In a large scale lazy multi-master replication architecture, the load balancing of transactions may improve the overall performance by choosing the best node to execute a transaction or query [GNPV02].

Table 6.1: Lazy Replication Parameters

Node fault tolerance is easy to implement [PS00] in the replication solutions presented in Chapters 2 and 3 because the algorithms rely on logs to keep track of propagated and received messages. Thus, in case of failures, the system is not blocked because there is no voting scheme and, upon recovery, the logs are used to resynchronize the recovering node.

P2P applications make data management much more difficult. Peers can leave and join the system dynamically. As the scale of P2P system gets very large, the probability of failures increases. P2P data replication must also be more general and we do not focus specifically on relational tables and transaction consistency requirements, as in preventive replication. Instead, we focus on P2P collaborative applications with some semantics, and general data objects. However, to enable the deployment of such applications in P2P networks, it is required a mechanism to deal with their high data sharing in dynamic, scalable and available way. Previous work on optimistic replication has mainly concentrated on centralized systems. Centralized approaches are inappropriate for a P2P setting.
due to their limited availability and vulnerability to failures and partitions from the network. We focused on the design of a reconciliation algorithm designed to be deployed in large scale cooperative applications, such as P2P Wiki. Our main contribution was a distributed reconciliation algorithm designed for P2P networks (P2P-reconciler). Other important contributions are: a basic cost model for computing communication costs in a DHT overlay network; a strategy for computing the cost of each reconciliation step taking into account the cost model; and an algorithm that dynamically selects the best nodes for each reconciliation step. Furthermore, since P2P networks are built independently of the underlying topology, which may cause high latencies and large overheads degrading performance, we also propose a topology-aware variant of our P2P-reconciler algorithm and show the important gains on using it. Our P2P-reconciler solution enables high levels of concurrency thanks to semantic reconciliation and yields high availability, excellent scalability, with acceptable performance and limited overhead. In addition, our topology aware approach improves the basic P2P reconciler by 50%, which is a very impressive result. This last result encouraged us to use topology awareness in current research work. This context corresponds to that of Chapter 4.

Distributed Hash Tables (DHTs) provide a scalable solution for data sharing in P2P systems. To ensure high data availability, DHTs typically rely on data replication, yet without data currency guarantees. Supporting data currency in replicated DHTs is difficult as it requires the ability to return a current replica despite peers leaving the network or concurrent updates. We give a complete solution to this problem. We propose an Update Management Service (UMS) to deal with data availability and efficient retrieval of current replicas based on timestamping. For generating timestamps, we propose a Key-based Timestamping Service (KTS) which performs distributed timestamp generation using local counters. Through probabilistic analysis, we compute the expected number of replicas which UMS must retrieve for finding a current replica. Except for the cases where the availability of current replicas is very low, the expected number of retrieved replicas is typically small, e.g. if at least 35% of available replicas are current then the expected number of retrieved replicas is less than 3. This context corresponds to that of Chapter 5.

We chose to develop our replication solutions of chapter 4 and 5 on top of DHT networks which enable to index data objects through a key value that may have some semantic significance. Using a DHT, data is uniformly distributed over the network, which is a good basis for scaling up and load balancing. In addition, fault-tolerance relies on the DHT fault tolerance. In our solutions, we assumed that the lookup service of the DHT does not behave incorrectly, that is, given a key k, it either finds correctly the responsible for k or reports an error, e.g. in the cases of network partitioning where the responsible is not reachable. To support this last assumption, network must be reliable and bounds must be approximatively known in order to have a reliable DHT stabilization algorithm. Finally, we also considered the use of some kind of detector [LCGS05]. These assumptions are quite acceptable in P2P dynamic networks [LCGS05]. To guarantee 100% of consistency, we would need to implement complex fault tolerance protocols [OV99] based on quorums, or some specific group communication
service on the DHT overlay level. However, these solutions are known not to scale up well, and do not behave well in dynamic environments. This lesson was learned in the context of Chapters 4 and 5.

6.2 Current and Future Work

Based on our previous work we just described and faced with some new challenges, we now present our perspectives in current and future work.

6.2.1 P2P Logging and Timestamping for Reconciliation (P2P-LTR)

As part of our current and future work, we consider the use of KTS (see Chapter 5) as a distributed P2P timestamper for general collaborative applications. For instance, consider several Xwiki users who update documents in parallel in a multi-master replication approach. The reconciliation of these updates needs to establish a total order on the updates to be applied at each master peer to provide eventual consistency. Alternatively to semantic reconciliation, we adopt a text editing reconciliation algorithm based on operational transforms such as So6 [MOSI03, SCF98]. For the reconciliation engine, one solution to provide total order is to rely on a centralized timestamper node that also stores the log of reconciled updates. However, the timestamper node may be a single point of failure and performance bottleneck. In this context, we now address three new requirements:

- Continuous P2P Timestamping; such that difference between the timestamps of any two consecutive updates be one;
- P2P-Log service, necessary to store the timestamped updates (log) in the DHT;
- Retrieval service to safely find the continuous timestamps updates stored in P2P-Log, used later on to perform document reconciliation.

We propose P2P-LTR service that addresses these new requirements. Concerning the Timestamps must be continuous (the difference between the timestamps of any two consecutive updates is one) instead of in monotonically increasing order. This allows Xwiki users to safely get the next missing patches of updates in the DHT (stored at log peers). So given the last timestamp value on a document \( d \), seen locally, the master asks the timestamper responsible peer of \( d \) to provide the last timestamp it gave to any other multi-master peer of \( d \). If this value is greater than the master local timestamp value, then the master of \( d \) gets all missing timestamped updates stored previously in the DHT. Thus the DHT acts as a highly available distributed log. Hence updates performed by masters are indexed using the document key and its timestamp value. We are currently working on this research topic, addressing some fault-tolerance issues and developing a prototype of P2P-LTR.

To measure the reliability of P2P-LTR we plan to implement and run exhaustively our solution over the PlanetLab platform [Pla]. PlanetLab makes it easy to deploy the DHT we use (OpenChord) [OCH] as it lets Java RMI call cross firewalls. We expect that in practice eventual consistency may be
violated rarely. However, we also accept that for the type of applications we consider a low level of inconsistency is acceptable (missing updates, out of order updates) and that the users can manage it. We plan to investigate the management of quality of data in such contexts.

6.2.2 P2P Caching
Motivated by the cost models proposed in our previous work on the P2P-reconciler, we currently focus on reducing P2P network traffic by combining different techniques: search strategies, caching placement and location awareness for cache management in unstructured and structured systems.

Index Caching

Despite the emergence of sophisticated overlay structures, unstructured P2P systems remain highly popular and widely deployed. They exhibit many simple yet attractive features, such as low-cost maintenance and high flexibility in data placement and node neighborhood. Unstructured P2P systems are heavily used for file-sharing communities due to their capacity of handling keyword queries i.e. instead of lookup on entire filenames. However, some studies [SGDGL02] observed that the P2P traffic is mainly composed of query messages and contributes the largest portion of the Internet traffic.

The principal cause of the heavy P2P traffic is the inefficient search mechanism, blind flooding, which is commonly employed in unstructured P2P networks. Many researchers have focused on this critical issue that may compromise the benefits of such systems by drastically limiting their scalability. In fact, inefficient searches cause unnecessary messages that overload the network, while missing requested files. Several analyses [P02, LBBS02, Scrip] found the P2P file-sharing traffic highly repetitive because of the temporal locality of queries. They actually observed that most queries request a few popular files and advocated the potential of caching query responses, to efficiently answer queries without flooding over the entire network (a query response holds information about the location of the requested file).

However, searches in general, suffer significantly from the dynamic nature of P2P systems where nodes are run by users with high autonomy and low availability. In fact, it is rather impossible to ensure the availability of a single file copy and thereby to satisfy queries for this file. In P2P file sharing, a node that requested and downloaded a file, can provide its copy for subsequent queries. As a consequence, popular files, which are frequently requested, become naturally well-replicated [CRBL+03]. Hence, search techniques should leverage the natural file replication to efficiently find results with minimum overhead.

Another important factor that worsens the traffic issue consists in constructing P2P overlays without any knowledge of the underlying topology. A typical case that illustrates this problem is the following: a query can be directed to a copy of the desired file which is hosted by a physically distant node, while other copies may be available at closer nodes. Hence, file downloads can consume a
significant amount of bandwidth and thereby overload the network. In addition, the user experience
dramatically degrades due to the relatively high latency perceived during transfer.

Our proposal to reduce P2P network traffic is based on DiCAS [WXLZ06], an index caching and
adaptive search algorithm. In DiCAS, query responses are cached, in the form of file indexes, in
specific groups of nodes based on a specific hashing of the filenames. Guided by the predefined
hashing, queries are then routed towards nodes which are likely to have the desired indexes. However,
DiCAS is not optimized for keyword searches which are the most common in the context of P2P file
sharing. Moreover, caching a single index per file does not solve the problem of file availability given
the dynamic nature of P2P systems, while it may overload some nodes located by previous queries.
DiCAS also lacks topological information to efficiently direct queries to close nodes.

Aiming at reducing the P2P redundant traffic and addressing the limitations of existing solutions,
we propose a solution [EPV07] that leverages the natural file replication and incorporates topological
information in terms of file physical distribution, when answering queries. To support keyword
searches, a Bloom filter is used to express keywords of filenames cached at each node, and is then
propagated to neighbors. A node routes a query by querying its neighbors' Bloom filters. To deal with
issues concerning availability and workload, a node caches several indexes per file along with
topological information. As a consequence, a node answers a query by providing several possibilities,
which significantly improves the probability of finding an available file. In addition, based on the
topological information, we expect that queries are satisfied in a way that optimizes the file transfer
and thus the bandwidth consumption. Our simulations shows that the cache hit and download distance
is improved by using our approach with acceptable overhead.

**P2P Web Caching**

In the next step of our research in P2P caching, we propose to exploit a DHT to share content storage
[RCFB07]. Much research work has been on addressed the search efficiency issue, including the
designs of Chord, Tapestry, Can, etc. In these approaches, each peer and its stored contents are
organized using a DHT. For a system with $N$ nodes, the search cost (i.e. number of lookup hops) is
bounded by $O(\log N)$. For the current search solutions in the structured P2P, all peers are assumed to
submit queries to uniformly search the contents stored in all peers. However, this assumption is not
valid in practice. Often, the popularities of the contents are skewed. For example, web requests on the
Internet space are highly skewed with a Zipf-like distribution. Therefore, this skewed popularity
causes unbalanced workload. In addition, due to the limited bandwidth, even though the search cost to
some hot peers is still bounded by $O(\log N)$ hops, there can be a long latency for getting the data.

One solution to improve the workload balance is to replicate these popular contents in the best
nodes which requires to address two key problems related to caching the replicas in structured P2P
systems: where and how to cache the replicas of popular contents.
6.2.3 P2P Data Streaming

Recent years have witnessed major research interest in data stream management systems. A data stream is a continuous and unbounded sequence of data items. There are many applications that generate streams of data including financial applications, network monitoring, telecommunication data management, sensor networks, etc. Processing a query over a data stream involves running the query continuously over the data stream and generating a new answer each time a new data item arrives. Due to the unbounded nature of data streams, it is not possible to store the data entirely in a bounded memory. This makes difficult the processing of queries that need to compare each new arriving data with past ones. We are interested in systems which have limited main memory but that can tolerate an approximate query result which has a maximum subset of the result.

A common solution to the problem of processing join queries over data streams is to execute the query over a sliding window [GO03] that maintains a restricted number of recent data items. This allows queries to be executed in a finite memory and in an incremental manner by generating new answers when a new data item arrives.

In current research, we address the problem of computing approximate answers to windowed stream joins over data streams. Our solution [PAPV08] involves a scalable distributed sliding window that takes advantage of the free computing power of DHT networks and can be equivalent to thousands of centralized sliding windows. Then, we propose a mechanism called DHTJoin, which deals with efficient execution of join queries over all data items which are stored in the distributed sliding window. DHTJoin combines hash-based placement of tuples in the DHT and dissemination of queries using a gossip style protocol.

Abstract. Many distributed database applications need to replicate data to improve data availability and query response time. The two-phase commit protocol guarantees mutual consistency of replicated data but does not provide good performance. Lazy replication has been used as an alternative solution in several types of applications such as on-line financial transactions and telecommunication systems. In this case, mutual consistency is relaxed and the concept of freshness is used to measure the deviation between replica copies. In this paper, we propose two update propagation strategies that improve freshness. Both of them use immediate propagation: updates to a primary copy are propagated towards a slave node as soon as they are detected at the master node without waiting for the commitment of the update transaction. Our performance study shows that our strategies can improve data freshness by up to five times compared with the deferred approach.

Key words: Data replication – Distributed databases – Performance evaluation

1 Introduction

In a distributed database system, data is often replicated to improve query performance and data availability. Performance is improved because replica copies are stored at the nodes where they are frequently needed. Availability is improved because replica copies are stored at nodes with independent failure modes. An important goal of concurrency control for a replicated database system is to achieve replica transparency. That is, as far as the users are concerned, a replicated database system should behave like a single copy database. Therefore, the interleaved execution of transactions on a replicated database should be equivalent to a serial execution of these transactions on a single copy database. Hence, one-copy serializability is enforced and replica consistency is achieved. Transaction processing in replicated databases has been well studied in [BHGG87]. Several protocols such as two-phase commit have been proposed to achieve replica consistency [Gif79, Tho79, BHGG87]. Almost all commercially available distributed database systems provide two-phase commit as an option [Sch76] to guarantee the consistency of replicated data.

A central problem of several database applications with real-time constraints, such as telecommunication systems, operational data stores [Inm96] or on-line financial transactions [Sha97], is to guarantee a high level of performance. For example, in a global trading system distributed over a wide-area network where exchange rates are replicated, it is crucial to have fast access to replicated data from any trader location. In addition, a change to a rate by a trader at a location must be propagated as fast as possible to all other locations to refresh replicated data. With a two-phase commit protocol (henceforth 2PC), an update transaction that updates a replica of an object is committed only after all nodes containing a corresponding replica copy agree to commit the transaction, thereby enforcing that all replica copies are mutually consistent. This approach is often referred to as tight consistency or synchronous replication [CRR96]. Synchronous replication has some drawbacks in practice [Mo96, Sch76]. Many database system vendors indicate that in numerous applications such as the ones we are interested in 2PC is impractical. The major argument is that its reliance on 100% system availability makes maintaining a productive level of transaction throughput for distributed replication impossible.

A good overview of replication capabilities of some commercially available distributed database systems can be found in [Gol94]. Systems like Sybase 10 [Mo96], Oracle 7 [Dav94b] and IBM Datapropagator Relational [Dav94a] support synchronous replication as well as an optional protocol that defers the updates of replicas. The deferred update protocols support loose consistency [Mo96] by allowing some replica copies to be inconsistent for some time. This approach is often referred to as asynchronous or lazy replication. Lazy replication provides better responsiveness since the waiting operations associated with multisite commit protocols are avoided.

* This work was partially supported by Esprit project EP 22469DWQ “Foundations for Data Warehouse Quality”.
With lazy replication, a transaction can commit only after updating at least one replica at some node. After the transaction commits, the updates are propagated towards the other replicas which are then updated in separate refresh transactions. Thus, this scheme relaxes the mutual consistency property of 2PC. Furthermore, the interval of time between the execution of the original update transaction and the corresponding refresh transactions may be large due to the propagation and execution of the refresh transactions.

The degree of freshness indicates the proportion of updates that are reflected by a given replica but have nevertheless been performed on the other replica copies.

In this paper, we address the problem of freshness in lazy replication schemes. We present a lazy master replication framework and assume a functional architecture with one master and multiple slave nodes. We propose a propagation strategy, called immediate-propagation, which works as follows: updates to a replica at some master node are immediately propagated towards the other replica copies held by slave nodes without waiting for the commitment of the original update transaction. Specifically, we propose two variants: immediate-immediate and immediate-wait. With immediate-immediate, a refresh transaction is started at a slave node as soon as the first update operation is received from the master node. With immediate-wait, a refresh transaction is started at a slave node after the complete reception of all updates (of the same transaction) from the master node. We present experimental results that demonstrate the improvement of freshness brought by these strategies with respect to a deferred strategy, as used by several commercial relational database systems.

This paper is a significantly extended version of [PSdM98]. The extensions are the following. First, we present in more details the update propagation algorithms and introduce the recovery procedures to deal with nodes failures. Second, we extend our performance evaluation by measuring query response times, the impact of freshness on the immediate strategies when transactions abort and the impact of freshness for different network delays. Finally, we include a comparison with related work.

The rest of this paper is structured as follows. Section 2 introduces our replication framework and basic definitions. Section 3 presents the system architecture of master and slave nodes used by our update propagation strategies. Section 4 describes the deferred strategy and the immediate strategies. Section 5 presents our performance evaluation. Section 6 discusses related work. Finally, Sect. 7 concludes.

2 Lazy master framework

With lazy master replication, updates on a primary copy are first committed at the master node. Then, each secondary copy is updated asynchronously, in a separate refresh transaction. A replication design typically includes the definition of the data to be replicated, the number of replica copies (i.e., primary and secondary copies), the nodes at which replica copies must be placed and others characteristics. In [PV98], we use a variety of terms to define a replication design. However, several terms are ambiguous and some others are still missing to make clear the characterization of a replication design. In this section, we define a framework that can precisely specify a lazy master replication design.

Four parameters characterize our framework: ownership, propagation, refreshment and configuration. However, the parameters we present are also valid for lazy group replication. We use the term lazy master replication scheme to refer to a replication design that fits in our framework. Therefore, whenever the four parameters are set, a replication scheme is established. We do not consider how to choose the data to be replicated since we consider that this involves the knowledge of the semantics of the distributed application.

The ownership parameter [GHOS96] defines the node capabilities for updating replica copies. A replica copy that is updatable is called a primary copy (denoted by capital letters), otherwise it is called a secondary copy (denoted by lowercase letters). In the remainder of this paper, we assume that replica copies are relations. For each primary copy, say \( R \), there is a set of secondary copies \( r_1, r_2, \ldots \). We refer to the set of primary and secondary copies as replica copies. In addition, we sometimes use the term replicated data instead of replica copies. We identify three types of nodes: Master, Slave and MasterSlave. Whenever a node stores only primary copies, it is referred to as a master node. Similarly, whenever a node stores only secondary copies it is called a slave node. Finally, a node that stores both primary and secondary copies is called a MasterSlave node.

We assume familiarity with transactional concepts [BHIG87]. We focus on three types of transactions that read or write replica copies: update transactions, refresh transactions and queries. An update transaction (denoted by \( T \)) updates a set of primary copies \( R, S, \ldots \). Each time a transaction is committed, a timestamp (denoted by \( C \)) is generated.

A refresh transaction (denoted by \( R(T) \)) is composed by the serial sequence of write operations performed by an update transaction \( T \). A refresh transaction is used to update (henceforth refresh) at least one secondary copy. Finally, a query, \( Q \), consists of a sequence of read operations on secondary copies. We assume that once a transaction is submitted for execution to a local transaction manager at a node, all conflicts are handled by the local concurrency control protocol.

The configuration parameter defines the component nodes of a replication scheme. For instance, a \( IMasterSlaves \) configuration, typically called data dissemination, consists of a replication scheme with a single master node, \( i \), and \( n \) slaves of \( i \). In this paper, we focus on \( IMasterSlaves \) configurations.

The propagation parameter defines “when” the updates to a primary copy must be multicast (henceforth propagated) towards the nodes storing its secondary copies. We focus on two types of propagation: deferred and immediate. When using a deferred propagation strategy, the serial sequence of writes on a set of primary copies performed by an update transaction is propagated together within a message \( M \), after the commitment of \( T \). When using an immediate propagation, each write operation performed by a transaction, for instance \( T \), is immediately propagated inside a message \( m \), without waiting for the commitment of the original update transaction \( T \).

The refreshment parameter defines when the submission of a refresh transaction starts with respect to a propagation.
strategy. We consider three trigger modes: deferred, immediate and wait. The couple formed by the propagation and the trigger mode determines a specific update propagation strategy. For instance, with a deferred-immediate strategy, propagation involves the sending of an RT towards each slave node which, as soon as it is received at a slave node, is submitted for execution. With immediate-immediate, propagation involves the sending of each write performed by a T towards each slave node, without waiting for the commitment of the original update transaction. At a slave node, a refresh transaction is started as soon as the first write operation is received from the master or MasterSlave node. Finally, immediate-wait is similar to immediate-immediate, except that a refresh transaction is submitted for execution only after the complete reception of all write operations of the original update transaction. Table 1 shows the update propagation strategies we focus on.

In our framework, we assume that messages are exchanged among the nodes of the replicated system through a reliable FIFO multicast protocol\(^1\) [HT94] because it is one of the most simple multicast protocols.

### 3 System architecture

The objective of our architecture is to maintain the autonomy of each node. This means that neither the local transaction management protocols nor query processing are changed to support lazy master replication. Each node, whether master or slave, supports a database system and three components. The first component is the replication module, which itself consists of three components: Log Monitor, Propagator and Receiver. The second component is the Refresher, which provides different qualities of service by implementing different refreshment strategies to update secondary copies. The last component, the Network Interface, is used to propagate and receive messages on the network. For simplicity, it is not shown in Fig. 1 and need not be discussed in this paper. We now present in more details the functionality of these components:

**Log Monitor.** It implements log sniffing [SKS86, KR87, Moi96], which is a procedure used to extract the changes to a primary copy by reading sequentially the contents of a local history log (denoted by \(H\)). We do not consider any particular log file format in our study. However, we safely assume that a log record contains all the information we need such as timestamp, primary Id, and other relevant attributes (see Chap. 9 of [GR93] for more details). When the log monitor finds a write operation on \(H\), it reads the corresponding log record from \(H\) and writes it into a stable storage called input log that is used by the Propagator. The reason we impose copying the history log entries to the input log is discussed below, when we present the Propagator’s functionality. We do not deal with conflicts between the write operations on the history log and the read operations performed by the Log Monitor since this procedure is well known and available in commercial systems [Moi96].

**Receiver.** It implements message reception at the slave node. Messages coming from different masters are received through a network interface that stores them in a reception log. The receiver reads messages from the reception log and stores them in pending queues. The contents of these queues form the input to the Refresher. A slave node detects its master node failure using timeout procedures implemented in the network interface. The node recovery procedures related to the Receiver are discussed in Sect. 4.3.

**Propagator.** It implements the propagation of messages that carry log records issued by the Log Monitor. Both types of messages are written in the input log. After correctly propagating a message, its contents is written inside the propagation log. If a node failure occurs during message propagation (i.e., before writing the message contents inside the propagation log), the input log is used to re-propagate the lost message at node recovery time. The Propagator continuously reads the records of the input log and propagates messages through the network interface. A master node is able to detect failures of its slave nodes using the network interface. The node recovery procedures related to the Propagator are discussed in Sect. 4.3.

**Refresher.** It implements refreshment strategies that define when refresh transactions are executed. For each slave node, there is a pending queue \(i, j, \ldots\). Each pending queue stores a sequence of messages (write operations) comming from a specific master node (see Fig. 1). The Refresher reads the contents of each pending queue and, following some refreshment strategy, executes refresh

---

1. Messages are received in the same order as they are propagated.
transactions to update the set of secondary copies. A refresh transaction execution is performed by submitting each write operation to the local transaction manager. Since we focus on 1Master-nSlaves configuration, we consider a single pending queue.

4 Update propagation strategies

We consider three update propagation strategies: deferred-immediate, which is based on the common approach used by lazy master replication schemes [Moi96], and our immediate-immediate and immediate-wait strategies. In this section, we present them with respect to our architecture. We first present the deferred and immediate propagation strategies that establish the basis for other strategies. Without loss of generality, we present our algorithms for a 1Master-1Slave configuration for a single primary copy R.

4.1 Propagation

To preserve serializability, the Log Monitor reads log records from H in the order they were written. It is worth mentioning that the algorithm used to manage H in the local database system is orthogonal to our strategies and has no impact on the way they function. The Propagator also reads log records from the input log in the order they were written and propagates them in serial order. Each log record stored in both H and the input log carries the information necessary to perform an operation, that is, the following attributes [GR93]: timestamp, primary id, tuple id, field id, operation, new value.

The master identifier, primary id, identifies the primary copy R that is updated at the master node. Tuples are identified by their primary key. In addition, the updated field within a tuple is identified by field id. Next, operation identifies the type of operation (update, delete, insert, abort or commit) performed. In case of an update operation, new value contains the new value of the field being updated. When there is no ambiguity, we sometimes use the term operation instead of log record.

The Propagator implements the algorithm given in Fig. 2. With immediate propagation, each write operation, \( w_i \), of R, by transaction \( T \) is read from the input log and forwarded by a propagate function in a message \( m_i \) containing the input log record to the slave holding a copy \( r \). Thus, for every slave node, there will be as many messages as write operations in \( T \). The performance impact of the possibly large number of messages generated is analyzed in Sect. 5. It is important to note that concurrent update transactions at the master produce an interleaved sequence of write operations in \( H \) for different update transactions. However, write operations are propagated in the same order as they were written in the input log to preserve the master serial execution order. Update transaction’s abort and commit at a master are also detected by the Log Monitor.

With deferred propagation, the sequence \( w_1, w_2, ..., w_n \) of operations on R performed by transaction \( T \) is packaged within a single message (denoted by \( M_i \)) that is propagated to the slave holding \( r \), after reading \( T \)’s commit from the

Propagator

input: Input Log
output: messages sent to slave nodes

then
add \( o \) to its associated vector \( RV \);
if \( o = \text{commit} \)
then
add \( o \) to its vector \( RV \);
submit \( RV \) as an \( RT \);
if \( o = \text{abort} \)
then
discard the vector associated with \( o \);
for ever.
end.

Fig. 3. Immediate-wait algorithm for queue \( q_r \).
4.2 Reception and refreshment

Each Receiver reads the messages $M_i$ in their reception order from the reception log. In addition, each Receiver checks the master identifier primary_id to select in which queue to store the log record(s) that each message carries, whenever there is more than one master node. Since we consider a single master node and primary copy $R$, we simply use $q_r$ to denote the pending queue that stores the messages to update $r$. We assume that when a message carries a sequence, this sequence is stored as a single record in the queue.

To update a secondary copy $r_i$, the Refresher continuously reads the pending queue, $q_r$, seeking for new incoming records. With deferred-immediate, the Refresher reads a sequence $w_1, w_2, ..., w_n$ within a single message from $q_r$ and subsequently submits it as a refresh transaction to the local transaction manager. The effect of the serial execution order of update transactions $T_1, T_2, ..., T_k$ performed at the master is preserved at the slave because the corresponding refresh transactions $RT_1, RT_2, ..., RT_k$ are performed in the same order.

With immediate-immediate, each time an operation is read from a queue it is subsequently submitted to the local transaction manager as part of some refresh transaction. Here again, for the same reasons as before, the effect of the serial execution order of the update transactions performed at the master is preserved. When an abort operation for a transaction $T$ is read by the Refresher, it is also submitted to the local transaction manager to abort $RT$.

With immediate-wait, refreshment is done in two steps. In the first step, a message is read from $q_r$ exactly as with immediate-immediate. However, each operation associated with a transaction $T$ is stored into an auxiliary data structure, called a reception vector (denoted by $RV$). Thus, there is one vector per transaction and each element of a vector is an operation. When a commit operation for a transaction $T$ is read from queue $q_r$, it is appended to the corresponding vector $RV$ and a refresh transaction $RT$ is formed with the sequence of operations contained in $RV$, and submitted to the local transaction manager.

The period of time delimited by the reading, in a queue $q_r$, of the first operation for transaction $T$, and the reading of the commit operation for $T$, is called the wait period for $RT$. Figure 3 summarizes the algorithm executed by the Refresher for a given queue $q_r$ using immediate-wait.

For all the three strategies, when a refresh transaction $RT$ is committed, the Refresher marks all the messages $M_i$ or $m_i$ in the reception log as processed.

4.3 Dealing with node failures

We now present the connection and node recovery protocols used to recover from node failures. They are based on those used for transaction recovery (see [GR93]). Thus, we introduce only the additional features needed for our replication scheme. We first present how a master node initializes a connection with a specific slave node. Then, we show how slave and master node failures are handled. Since we assume that network omissions are bounded and taken into account by the multicast protocol, we can ignore network failures. For pedagogical reasons, whenever necessary, we make clear the distinction between master and slave node procedures.

4.3.1 Initialization

To start update propagation towards a slave node, a master node must first initiate a connection. When update propagation is completed, the master can close the connection. In order to preserve the autonomy of each DBMS, connection and disconnection requests are captured by our replication module through the local history log (denoted by $H$). The result of a connection or disconnection request is done using the connection table, which we describe below. Connection and disconnection are requested using the following functions.

**Connect**($Master_id$, $Slave_id$, $Replica_id$): $Master_id$ requests a connection to $Slave_id$ in order to start update propagation on $Replica_id$. A corresponding log record is generated and written in the local history log of $Master_id$ with the following information:

```
<"Connect", Master_id, Slave_id, Replica_id >.
```

**Disconnect**($Master_id$, $Slave_id$, $Replica_id$): $Master_id$ requests a disconnection to $Slave_id$ in order to stop update propagation on $Replica_id$. A corresponding log record is generated and written in $Master_id$ local history with the following information:

```
<"Disconnect", Master_id, Slave_id, Replica_id >.
```

Each node $i$ (master or slave node) keeps control of its connections using a connection table stored in the local DBMS. Each entry of this table corresponds to an established connection. The main attributes of this table are $Node_id$, $Replica_id$ and $Status$. $Node_id$ identifies a node that is connected to node $i$ and $Replica_id$ identifies the local replica copy involved in a specific connection. The $status$ attribute indicates the current status of the connection. The interpretation of each attribute at a master or slave node is as follows.

**Master**: $Replica_id$ is a primary-copy identifier. The Log Monitor reads the connection table to check which primary copies it must monitor. $Node_id$ is a slave node identifier associated with a specific connection. By reading the set of slave node identifiers from the connection table, the Propagator is able to request a connection or disconnection and detect a slave node failure. The $status$ attribute indicates whether a connection is active or inactive. The connection table may be read and updated by the Propagator and Log Monitor, in addition, it may be read by the local DBMS users.

**Slave**: $Replica_id$ is a secondary-copy identifier. $Node_id$ identifies a master node associated with a specific connection. A slave node uses the connection table to identify its masters in order to create and destroy pending queues and detect master node failures. The $status$ attribute indicates whether a connection is active or inactive. The connection table may be read and updated by the Receiver and read by the local DBMS users.

Node initialization starts by the creation of a connection table a each node. Recall that at each slave node, the
Refresher manages a set of pending queues. Each pending queue may store a sequence of write operations used to update a set of secondary copies. When a master node is inactive for propagating the updates on a specific primary copy, a Disconnect record is stored in the corresponding pending queue at each slave node indicates that the queue is not available for refreshment.

Connection and disconnection are handled as follows. When the Log Monitor reads a Connect (or Disconnect) record from $H$, it writes it in the input log. Then, the Propagator reads the Connect (or Disconnect) record from the input log, and propagates the Connect (or Disconnect) message towards Slave$_id$. In case of connection, it creates a new connection entry in the local connection table. Otherwise, it deletes the corresponding connection from the connection table.

When a slave node receives the Connect message, its Receiver creates a new connection entry in the local connection table and records the contents of the Connect message into the pending queue corresponding to the master node. Thus, a Connect record informs the Refresher that the queue is available for refreshment. When a slave node receives the Disconnect message, its Receiver deletes the corresponding connection entry from the local connection table and records the contents of the Disconnect message in the corresponding pending queue. Thus, a Disconnect record informs the Refresher that the queue is not available for refreshment.

Disconnection can be granted only after all the messages sent by the master have been received by the slave. This is easy because messages are propagated using a FIFO multicast protocol. Thus, when a slave receives a Disconnect message, it is necessarily the last one for the corresponding connection.

4.3.2 Recovery

We now present how master and slave nodes recover after a node failure.

Slave failure

Slave failure is managed as follows. When a slave node fails, all the connected masters must stop sending messages to it. Failure detection is done by each master Propagator by periodically checking whether the slave is up using the network interface.

Slave recovery is performed in two steps. First, after system recovery, the Receiver writes in each pending queue a Reconnect record of the form:

\[ <"\text{Reconnect"}, \text{Master}_id, \text{Slave}_id, \text{Replica}_id, \text{Message}_id > \]

$\text{Message}_id$ indicates the last message $M_i$ or $m_i$ (this is easily read by the Receiver based on the reception log) and is used as re-synchronization point to re-start the master propagation and the slave refreshment activities. The Refresher reads a Reconnect record and is aware that the connection with $\text{Master}_id$ is being re-established. In the second step, the Receiver re-establishes its pending connections. It does so by searching in the reception log for all messages received from $\text{Master}_id$ but not yet processed by the Refresher, and stores each message in the correct queue $q$.

Master failure

Master failure is handled as follows. When a master node fails, all the connected slave nodes detect the failure through their Receiver, which periodically checks for master node availability using the network interface. As soon as a master failure is detected, the slave Receiver writes a Fail record of the form

\[ <"\text{Fail"}, \text{Master}_id > \]

in the correct pending queue. This record informs the Refresher of $\text{Master}_id$ failure. When a master recovers, it re-establishes its connections by propagating a Reconnect message towards each slave node it was connected to. In this case, the $\text{Message}_id$ field is nil. When the slave node receives a Reconnect message, it stores its contents in the correct queue $q$. Thus, the Reconnect record indicates the Refresher of $\text{Master}_id$ recovery. The Receiver re-starts reception activities for $\text{Master}_id$. As in any database system, the propagation log and reception log are supposed to have enough disk space to deal with recovery.

Our node recovery protocol is non-blocking, because in case of a master failure, the slave refreshment activities on other secondary copies are not interrupted. Using the connection table, a user at a slave node can detect the failure of a master and make a choice on how to proceed with its replication activities. For instance, the user may decide to ignore the master failure at the expense of freshness.

5 Validation

To validate our update propagation strategies, we need to demonstrate their performance improvement. Performance evaluation of such strategies is difficult since several factors such as node speed, multiprogramming level, network bandwidth and others, have a major impact on performance. Some update propagation strategies have been evaluated analytically [GN95, GHOS96]. However, analytical evaluation is typically very complex and hard to understand. In addition, the results may not reflect the real behavior of the strategies under various workloads. Therefore, instead of doing performance analysis of our strategies, we prefer to use a simulation environment that reflects as much as possible a real replication context.

5.1 Simulation environment

There are many factors that may influence the performance of our strategies, for instance, the processing capability of the slave nodes and the speed of the network medium. We isolate the most important factors such as: (i) transaction execution time, reflected by the time spent to log the updates made by a transaction into the history log (denoted by $H$), (ii) refresh transaction (denoted by $RT$) propagation time, that is the time needed to propagate the necessary messages from a master to a slave, and (iii) refresh transaction execution time. Consequently, our simulation environment only focuses on
the components of a node architecture that determine these three factors. In the following, we present the component modules of the simulation environment.

5.1.1 Modules

Our simulation environment is composed by the following modules: Master, Network, Slave and a database server. The Master module simulates all relevant functionalities of a master node such as log monitoring and message propagation. The Network module implements and simulates the most significant factors that may impact our update propagation strategies such as the delay to propagate a message. The Slave module implements the most relevant components of the slave node architecture such as Receiver, Refresher and Deliverer. In addition, for performance evaluation purposes, we add the Query component in the slave module, which implements the execution of queries that read replicated data. We do not consider node failures in our performance evaluation because we focus on freshness improvement. Therefore, the reception log as well as the recovery procedures are not taken into account. Finally, a database server is used to implement refresh transactions and query execution.

Our environment is implemented on a Sun Solaris workstation in C language using pipes for inter-process communication. We use Oracle 7.3 to implement the database functionalities such as transaction execution, query processing and others.

5.2 Performance model

In this section, we formalize the concept of freshness needed for our performance evaluation. Then we present the parameters we considered in our experimentations, as well as the terms used to explain our results.

Freshness is formalized as follows. We may have different transaction sizes but we assume that their occurrence is uniformly distributed over time. Using this assumption of uniformity, we define the concept of shift to simplify the definition of degree of freshness. The shift of a query with respect to a refresh transaction is the difference between the number of committed update transactions of the refresh transaction and the number of committed refresh transactions on the refresh transaction.

Thus, we define the degree of freshness as

\[ f = 1 - \text{shift}(t_Q, r)/n(R); f \in [0, 1]. \]

Therefore, a degree of freshness close to 0 indicates that data freshness is bad, while a degree of freshness close to 1 indicates that data freshness is excellent. In the remainder of this paper, we use the terms freshness and degree of freshness interchangeably.

Update transactions may be executed in different ways. The density of an update transaction is the average interval of time (denoted by \( \epsilon \)) between write operations in the transaction. If, on average, \( \epsilon \geq c \), where \( c \) is a predefined system parameter, then \( T \) is said to be sparse. Otherwise, \( T \) is said to be dense. We focus on dense update transactions, i.e., transactions with a small time interval between each two writes. In addition, we vary the transactions arrival rate distribution (denoted by \( \lambda_q \)), which is exponential and reflected in the history log. Updates are done on the same attribute (denoted by attr) of a different tuple. Furthermore, we take into account that transactions may abort. Therefore, we define an abort probability (denoted by \( \text{abr} \)) of 0, 5%, 10%, 20% that corresponds to the percentage of transactions that abort in an experimentation. Furthermore, we assume that a transaction abort occurs after half of its execution. For instance, \( \text{abr} = 10\% \) means that 10% of the update transactions abort after the execution of half of its write operations.

Network delay is calculated by \( \delta + t \), where \( \delta \) is the network delay introduced to propagate each message and \( t \) is the on-wire transmission time. In general, \( \delta \) is considered to be non-significant, and \( t \) is calculated by dividing the message size by the network bandwidth [CFLS91]. In our experiment, we use a short message transmission time (denoted by \( t_{\text{short}} \)), which represents the time needed to propagate a single log record. In addition, we consider that the time spent to transmit a sequence of log records is linearly proportional to the number of log records it carries. The network delay to propagate each message, \( \delta \), is implicitly modeled by the system overhead from reading from and writing to sockets. The total propagation time (denoted by \( t_p \)) is the time spent to propagate all log records associated with a given transaction. Thus, if \( n \) represents the size of the transaction with immediate propagation, we have \( t_p = n \times (\delta + t_{\text{short}}) \), while, with deferred propagation, we have \( t_p = (\delta + n \times t_{\text{short}}) \). Network contention occurs when \( \delta \) increases due to the increase of network traffic. In this situation, the delay introduced by \( \delta \) may impact the total propagation time, especially with immediate propagation.

Refreshment time is the time spent to execute an RT. Update propagation time is defined as the time delay between the commitment of RT at the slave and the commitment of its corresponding T at the master. Query arrival rate distribution (denoted by \( \lambda_q \)) is exponential. Query size is supposed to be small and thus fixed to 5.

Refresh transaction execution time is a relevant factor in our simulation environment (see Sect.5.1) because it may delay by \( \delta \) a query Q execution time at time \( t_Q \). Meanwhile, the degree of freshness may be increased. Therefore, to measure freshness, we fix a 50% conflict rate for each

secondary copy because it gives high chances to have conflicting queries and refresh transactions. This means that each refresh transaction coming from the master node master nodes updates 50% of the tuples read by a query. Each time an update transaction commits, a database variable, called version\_master, is incremented. Similarly, each time a refresh transaction commits another database variable, called version\_slave, is incremented. For each query, the degree of freshness is computed by subtracting version\_slave from version\_master.

We compare the impact of using two concurrency control protocols on query response time. One protocol is the strict two-phase locking protocol (henceforth, S2PL), which may increase response time when a query conflicts with a refresh transaction. Since Oracle 7.3 does not implement S2PL, we simulate it using Oracle’s SELECT-FROM-WHERE statement followed by the FOR UPDATE option.

The second protocol is a multiversion protocol, which is implemented in different ways [BH87] by several commercial database systems. The main idea of a multiversion protocol is to increase the degree of concurrency between transactions through a mechanism that permits the execution of both a query and a transaction in a conflict situation. Here, we focus on the Snapshot-Isolation-based multiversion protocol available in Oracle 7.3. In this protocol, a transaction T executing a read operation on a data item always reads the most recent version of that data item that has been committed before the beginning of T, later called Start\_Timestamp of T. Therefore, T reads a snapshot of the database as at the time it started. Updates performed by transactions that are active after the time Start\_Timestamp are invisible to T. An important point is that, with a Snapshot Isolation multiversion protocol, queries never conflict with refresh transactions.

We define two types of update transactions. Small update transactions have size 5 (i.e., five write operations), while long transactions have size 50. To understand the behavior of each strategy in the presence of short and long transactions, we define four scenarios. Each scenario determines a parameter called long transaction ratio (denoted by ltr). We set ltr as follows:

- scenario 1: ltr = 0 (all update transactions are short),
- scenario 2: ltr = 30 (30% of the executed update transactions are long),
- scenario 3: ltr = 60 (60% of the executed update transactions are long),
- scenario 4: ltr = 100 (all transactions are long).

When ltr > 0, the value of Max is calculated using the average time spent to propagate a long transaction (50 \times t\_short). On the other hand, when ltr = 0, the value of Max is calculated using the average time spent to propagate a short transaction (5 \times t\_short).

Refresh transaction execution is performed on top of Oracle 7.3 using C/SQL. For simulation purposes, each write operation corresponds to an UPDATE command that is submitted to the server for execution. The definition and values of the parameters of the performance model are summarized in Tables 2 and 3. The results are average values obtained for the execution of 40 update transactions.

### 5.3 Performance evaluation

The goal of our experimentations is to understand the behavior of the three propagation strategies on low and bursty scenarios, since these workloads are typical of advanced applications. The first experiment presents our results for the low workload and the second one for the bursty workload. In the third experiment, we study the impact on freshness when update transactions abort. In the fourth experiment, we verify the freshness improvement of each strategy when the network delay to propagate a message increases. Finally, we discuss our results. Table 4 summarizes each experiment.
three strategies. Thus, during transactions completion of transactions goal Table 4.
times and the degree of freshness obtained for a low The goal of this experiment is to analyze the query response response times for the three strategies. The reason is that, on average, t+1. However, for higher ltr values, we have λi < tp for the three strategies. Thus, during Ti’s update propagation, some transactions T+1...T may be committed, thereby decreasing the degree of freshness. For all ltr values, the degree of freshness obtained with deferred-immediate and immediate-wait are close, because the refreshment time is near equal for these two strategies. Furthermore, the total propagation times are also close since there is no network contention.

With immediate-immediate, refreshment time is greater than that of other strategies because the time interval between the execution of two write operations, w_i and w_{i+1}, of RTi is impacted by t_{short}, δ and ε, thereby slowing down refreshment time. However, compared to the other two strategies, immediate-immediate update propagation time is smaller, because propagation and refreshment are done in parallel. That is, RTi execution starts after the reception of the first write done by Ti. Therefore, immediate-immediate is the strategy that always presents the best degree of freshness. For all strategies, the degree of freshness does not vary linearly with ltr since we are mixing transaction sizes and our freshness measure is based on transaction size.

With immediate-immediate, query response time may increase whenever a query conflicts with a refresh transaction, because propagation and refreshment are done in parallel. Therefore, refreshment time is impacted by the total propagation time. However, the chance of conflicts is reduced because λi ≈ λq. That is the reason why the mean query response times are not seriously affected when ltr = 30 (see Fig. 5). However, with ltr = 60 and ltr = 100, lock-holding times are longer due to the transaction size that increases the number of propagated messages, causing the increase in query response times. Figure 5 shows a situation (with ltr = 100) where response time may be doubled compared to immediate-wait. We only show the immediate-wait curve since response times for the deferred-immediate strategy are very close. When using a multiversion protocol, query response time for the three strategies in all cases is reduced to an average of 1.2 s.

5.3.1 Experiment 1

The goal of this experiment is to analyze the query response times and the degree of freshness obtained for a low update transaction arrival rate at a master node.

As depicted in Fig. 4, when ltr = 0, the degree of freshness is almost 1, i.e., replicas are almost mutually consistent with the three strategies. The reason is that, on average, λi ≈ t_p, that is the time interval between the execution of a Ti and a subsequent T_{i+1} is sufficiently high to enable completion of Ti’s update propagation before the commitment of T_{i+1}. However, for higher ltr values, we have λi < t_p for the three strategies. Thus, during Ti’s update propagation, some transactions T_{i+1}...T_{i+r} may be committed, thereby decreasing the degree of freshness. For all ltr values, the degree of freshness obtained with deferred-immediate and immediate-wait are close, because the refreshment time is near equal for these two strategies. Furthermore, the total propagation times are also close since there is no network contention.

With immediate-immediate, refreshment time is greater than that of other strategies because the time interval between the execution of two write operations, w_i and w_{i+1}, of RTi is impacted by t_{short}, δ and ε, thereby slowing down refreshment time. However, compared to the other two strategies, immediate-immediate update propagation time is smaller, because propagation and refreshment are done in parallel. That is, RTi execution starts after the reception of the first write done by Ti. Therefore, immediate-immediate is the strategy that always presents the best degree of freshness. For all strategies, the degree of freshness does not vary linearly with ltr since we are mixing transaction sizes and our freshness measure is based on transaction size.

With immediate-immediate, query response time may increase whenever a query conflicts with a refresh transaction, because propagation and refreshment are done in parallel. Therefore, refreshment time is impacted by the total propagation time. However, the chance of conflicts is reduced because λi ≈ λq. That is the reason why the mean query response times are not seriously affected when ltr = 30 (see Fig. 5). However, with ltr = 60 and ltr = 100, lock-holding times are longer due to the transaction size that increases the number of propagated messages, causing the increase in query response times. Figure 5 shows a situation (with ltr = 100) where response time may be doubled compared to immediate-wait. We only show the immediate-wait curve since response times for the deferred-immediate strategy are very close. When using a multiversion protocol, query response time for the three strategies in all cases is reduced to an average of 1.2 s.

5.3.2 Experiment 2

The goal of this experiment is to analyze the degree of freshness and the query response times obtained for the three strategies for a bursty transaction arrival rate.

As depicted in Fig. 6, when ltr = 0 (short transactions), the degree of freshness is already impacted because on average, λi < t_p. Therefore, during Ti’s update propagation, T_{i+1}, T_{i+2},...T_{i+r} may be committed. It is important to note that deferred-immediate may give a better degree of freshness compared to immediate-wait, in bursty workloads, because δ increases sufficiently to increase the immediate total propagation time. Therefore, the total propagation time of a short transaction using deferred propagation may be less than the total propagation time using immediate propagation. On the other hand, even with network contention, immediate-immediate yields a better degree of freshness than both deferred-immediate and immediate-wait, because refreshment begins after the reception of the first write.

When long update transactions are executed, the degree of freshness decreases because t_p increases and λi << t_p. Immediate-wait begins to improve and becomes better than deferred-immediate when ltr = 30, ltr = 60 and ltr = 100. This is because q_1 is quickly filled with a large number of

operations such that, when the Refresher reads $q_r$, seeking for a new $HT_i$, it may happen that all operations associated with $HT_i$ may have been already received and stored in $q_r$. In this case, the additional wait period of immediate-wait may be reduced to 0. This is clearly seen when $ltr = 100$ (all refresh transactions have the same size). Figure 7 shows a snapshot of the degrees of freshness for a sequence of queries $Q_1, Q_{i+1}, \ldots$ at times $t_{Q_1}, t_{Q_{i+1}}, \ldots$ when $ltr = 100$. For simplicity, we omit the time each query occurred since we are interested in the behavior of the degree of freshness. The results show that the degrees of freshness obtained with immediate-immediate and immediate-wait are close to equal. On the other hand, the degree of freshness of deferred-immediate decreases rapidly because there is no parallelism of tasks as with the immediate strategies. So, when update transaction sizes increase, update propagation times rise much more compared to the immediate strategies. This impacts the degrees of freshness much more seriously.

Response time is clearly impacted by the immediate-immediate strategy (see Fig. 8) for the same reasons as in Experiment 1. The difference here is that $\lambda_r < < \lambda_q$, therefore, the chances of conflicts between a query and a refresh transaction augment and the mean query response time increases much more, compared to the results obtained in the low workload case. This is well perceived when $ltr$ increases. Using a multiversion protocol, query response time for the three strategies in all cases is also reduced to an average of 1.2 s without a significant decrease of the degree of freshness.

5.3.3 Experiment 3

The goal of this experiment is to show the effects of transaction aborts on the degree of freshness. We consider a single master node in a bursty workload.

As shown in Fig. 9, for $ltr = 0$ and various values of $abr$ (5, 10, 20), the decrease of freshness introduced by update transactions that abort with immediate-immediate is insignificant. In the worst case, it achieves 0.2. This behavior is the same for other values of $ltr$ (30, 60, 100). The same behavior is also observed for immediate-wait. These results show that the time spent to discard the reception vectors and undo refresh transactions at a slave node are insignificant compared to propagation time. Therefore, for the immediate strategies, we may safely state that freshness is not affected in case of update transaction aborts.

With deferred-immediate, the degrees of freshness may even increase, because no processing is initiated at the slave node until the complete commitment and propagation of an update transaction. Therefore, while a transaction is aborting at the master node, the slave node may be catching up.

5.3.4 Experiment 4

The goal of this experiment is to show the impact of network delay for message propagation on the degree of freshness and query response times. We consider a single master node in a bursty workload.

Figure 10 compares the freshness results obtained when $\delta = 100 \text{ ms}$ and $\delta = 20 \text{ ms}$ ($\delta$ denotes the network delay to propagate a message). When $\delta = 20$ and $ltr = 100$, immediate-immediate improves 1.1 times better than deferred-immediate and when $\delta = 100$, immediate-immediate improves 5 times better. The improvements of immediate-wait compared to deferred-immediate are close to these two results. Similar results are obtained when $ltr = 60$. In addition, in the presence of long transactions, the decrease of freshness when $\delta = 100 \text{ ms}$ is significantly higher for immediate-wait and deferred-immediate compared to the results obtained when $\delta = 20 \text{ ms}$. This is because the higher the value of $\delta$ is, the longer it takes to propagate a refresh transaction and in average the values of $t_p$ may be much higher than $\lambda_q$. Finally, these experiments confirm the benefits of having tasks being performed in parallel when using immediate-immediate.

Figure 11 compares the response times obtained when $\delta = 100 \text{ ms}$ and $\delta = 20 \text{ ms}$. Whenever the value of $\delta$ increases, the locking time in conflict situations augments because the refreshment time is proportional to propagation time. When $\delta = 100 \text{ ms}$, the increase of query response is high when $ltr = 30$ but insignificant when $\delta = 20 \text{ ms}$.

5.4 Discussion

We now summarize and discuss the major observations of these experiments. With low workloads, the degree of freshness for one master node is slightly impacted if update transactions are dense and long. In this case, immediate-wait and deferred-immediate give similar degrees of freshness because their total propagation times are close. Immediate-immediate is the strategy that gives the best degree of freshness because propagation and refreshment are done in parallel. Immediate-immediate is the only strategy that may introduce an increase in query response time because propagation and refreshment are done in parallel. Therefore, in conflict situations, the increase of query response times may depend on $t_{short}$, $\epsilon$ and $\delta$. However, the mean query response time is not seriously affected because $\lambda_q > \lambda_l$. Therefore, the chances of conflicts are small.

When update transactions arrive in burst, the degree of freshness decreases much more in the presence of long transactions. The immediate-immediate strategy still yields
Fig. 9. Bursty workload - abort effects

Fig. 10. Increase of network delay - degree of freshness

Fig. 11. Increase of network delay - response time (1 master)
the best degree of freshness, even with network contention. When the value of \( \lambda t \) grows, immediate-wait gives results close to those of immediate-immediate. When all transactions are long, immediate-wait performs like immediate-immediate because each pending queue is quickly filled with operations due to the immediate propagation. Thus, the effect of the \( \text{wait period} \) of immediate-wait may be eliminated because the operations that compose a refresh transaction \( RT \) may be already available in \( q_r \) whenever the refresher seeks for a new refresh transaction. With deferred-immediate the degree of freshness is much more impacted, compared to immediate-immediate and immediate-wait because there is no parallelism advantage in improving the degree of freshness.

With immediate-immediate, the mean query response time may be seriously impacted by the parallelism of propagation and refreshment. When \( \lambda_q \gg \lambda_t \), the chances of conflicts increase much more compared to the case of low workload. Query response times are much lower with immediate-wait because there is no parallelism between propagation and refreshment. Here, the network delay to propagate each operation has an important role and the higher its value, the higher are the query response times in conflict situations. In any case, the use of a multiversion protocol on the slave node may significantly reduce query response times, without a significant decrease in the degree of freshness.

The abort of an update transaction with immediate-immediate and immediate-wait does not impact the degree of freshness since the delay introduced to undo a refresh transaction or discard a reception vector, respectively, are insignificant compared to the propagation time. Finally, the gains obtained with immediate-immediate and immediate-wait are much more significant when the network delay to propagate a single operation augments. This clearly shows the advantages of having tasks being executed in parallel.

Replication scheme A corresponds to lazy replication where all replica copies are updatable \((\text{update anywhere})\). In this case, there is group ownership of the replicas. The common update propagation strategy for this scheme is deferred-immediate. However, conflicts may occur if two or more nodes update the same replica copy. Policies for conflict detection and resolution have been based on timestamp ordering, node priority and other strategies. The problem with conflict resolution is that during a certain period of time, the database may be in an inconsistent state. Conflicts cannot be avoided, but their detection may happen earlier by using an immediate propagation.

Replication scheme B is the focus of our work. There are several refreshment strategies for this replication scheme. With on-demand refreshment, each time a query is submitted for execution, secondary copies that are read by the query are refreshed by executing all the refresh transactions that have been received. Therefore, a delay may be introduced in query response time. When group refresh is used, refresh transactions are executed in groups according to the application’s freshness requirements. With the periodic approach, refreshment is triggered at fixed intervals. At refreshment time, all received refresh transactions are executed. Finally, with periodic propagation, changes performed by update transactions are stored in the master and propagated periodically towards the slaves. Immediate propagation may be used with all refreshment strategies.

Incremental agreement is an update propagation strategy [CHKS95] that has some features in common with our proposed strategies. However, it focuses on managing network failures in replicated databases and does not address the problem of improving freshness. Refreshment is performed using the slave log, whereas we use the local transaction manager.

The goal of epidemic algorithms [TTP+95] is to ensure that all replicas of a single data item converge to a single final value in a lazy group replication scheme. Updates are executed locally at any node. Later, nodes communicate to exchange up-to-date information. In our approach, updates are propagated from each primary copy towards all its secondary copies instead.

In [AA95, ABGM90], authors propose weak consistency criteria based on time and space, e.g., a replica should be refreshed after a time interval of after ten updates on a primary copy. There, the concern is not anymore on fast refreshment, and hence these solutions are not adequate to our problem.

In [PMS99], we have formally analyzed and extended the configurations introduced here and focused on replica consistency in different lazy-master-replicated database configurations. For each configuration, we defined sufficient conditions that must be satisfied by a refreshment algorithm in order to be correct. We proposed a refreshment algorithm, which we proved to be correct for a large class of acyclic configurations. In this paper, we focus on freshness improvement for 1Master-nSlaves configurations only and provide extensive experimental results.

The timestamp message delivery protocol found in [Go192] implements eventual delivery for a lazy group replication scheme [GHO96]. It uses periodic exchange of messages between pairs of servers that propagate messages to distinct groups of master nodes. At each master node, incoming messages are stored in a history log (as initially proposed in [KR87]) and later delivered to the application in a defined order. Eventual delivery is not appropriate in our framework, since we are interested in improving data freshness.

The stability and convergence of replication schemes A and B are compared in [GHOS96] through an analytical
model. The authors show that scheme A has unstable behavior as the workload scales up and that using scheme B reduces the problem. They introduce several concepts such as lazy master and ownership, which we use. They also explore the use of mobile and base nodes. However, immediate propagation is not considered.

Formal concepts for specifying coherency conditions for replication scheme B in large-scale systems are introduced in [GN95]. The authors focus on the deferredimmediate strategy. The proposed concepts enable computing an independent measure of relaxation, called coherency index. In this context, the concept of version is closely related to our notion of freshness.

Freshness measures are related to coherency conditions that are widely explored in [AA95, ABGM90] and used in information retrieval systems to define when cached data must be updated with respect to changes performed on the central object.

[AKGM96] proposes several derived data refresh strategies such as no-batching, on-demand, periodic and others for derived data refreshment. Replica refreshment and derived data refreshment are done in separate transactions. The authors address freshness improvement, although they focus on the incoherence between derived data and the secondary copy.

Oracle 7.3 [HHB96] implements event-driven replication. Triggers on the master tables make copies of changes to data for replication purposes, storing the required change information in tables called queues that are periodically propagated. Sybase 10 replication server replicates transactions, not tables, across nodes in the network. The Log Transfer Manager implements log monitoring like our approach. However, these systems do not implement immediate propagation and there is no multi-queue scheme for refreshment.

7 Conclusion

In this paper, we addressed the problem of improving freshness in lazy master replication schemes. More specifically, we dealt with update propagation from primary copy to secondary copies. We presented a framework and a functional architecture for master and slave nodes to define update propagation strategies. Focusing on Master-nSlave configurations, we proposed two new strategies called immediate-immediate and immediate-wait, which improve over the deferred strategy of commercial systems.

To validate our strategies, we performed a thorough performance evaluation through a simulation using Oracle 7.3. The results indicate that, for short transactions, the deferred approach performs almost as well as immediate-immediate and immediate-wait. The strategies exhibit different freshness results when long transactions occur. In these cases, our strategies show much better results and the immediate-immediate strategy provides the best freshness results. For some important kinds of workloads, freshness may be five times better than that of the deferred strategy. On the other hand, immediate-wait only improves freshness when the update transaction arrival rate at the master is bursty. The downside of immediate-immediate is the increase of query response time due to the transaction blocking when there are conflicts between refresh transactions and queries. However, we argue that, using a multiversion concurrency control protocol at the slave node, this drawback can be drastically reduced without a significant loss of freshness.

The improvement shown by our immediate strategies should be beneficial to distributed applications with real-time constraints. For instance, in a global on-line financial trading application exchange rates are replicated. At each slave node, traders will always have a fresher “view of the world” and in many cases, the improvement will help avoiding wrong decisions.

Abstract. In a lazy master replicated database, a transaction can commit after updating one replica copy (primary copy) at some master node. After the transaction commits, the updates are propagated towards the other replicas (secondary copies), which are updated in separate refresh transactions. A central problem is the design of algorithms that maintain replica’s consistency while at the same time minimizing the performance degradation due to the synchronization of refresh transactions. In this paper, we propose a simple and general refreshment algorithm that solves this problem and we prove its correctness. The principle of the algorithm is to let refresh transactions wait for a certain “deliver time” before being executed at a node having secondary copies. We then present two main optimizations to this algorithm. One is based on specific properties of the topology of replica distribution across nodes. In particular, we characterize the nodes for which the deliver time can be null. The other improves the refreshment algorithm by using an immediate update propagation strategy.

Keywords: replicated data, distributed database, data mart, data warehouse, replica consistency, lazy replication, refreshment algorithm, correctness criteria

1. Introduction

Lazy replication (also called asynchronous replication) is a widespread form of data replication in (relational) distributed database systems [27]. With lazy replication, a transaction can commit after updating one replica copy. After the transaction commits, the updates are propagated towards the other replicas, and these replicas are updated in separate refresh transactions. In this paper, we focus on a specific lazy replication scheme, called lazy master replication [18] (also called Single-Master-Primary-Copy replication in [4]). There, one replica copy is designated as the primary copy, stored at a master node, and update transactions are only allowed on that replica. Updates on a primary copy are distributed to the other replicas, called secondary copies. A major virtue of lazy master replication is its ease of deployment [4, 18]. In addition, lazy master replication has gained considerable pragmatic interest because it is the most widely used mechanism to refresh data warehouses and data marts [8, 27].

However, lazy master replication may raise a consistency problem between replicas. Indeed, an observer of a set of replica copies at some node at time \( t \) may see a state \( I \) of
these copies that can never be seen at any time, before or after \( t \), by another observer of the same copies at some other node. We shall say that \( I \) is an inconsistent state. As a first example, suppose that two data marts \( S_1 \) and \( S_2 \) both have secondary copies of two primary copies stored at two different data source nodes. If the propagation of updates coming from different transactions at the master nodes is not properly controlled, then refresh transactions can be performed in a different order at \( S_1 \) and \( S_2 \), thereby introducing some inconsistencies between replicas. These inconsistencies in turn can lead to inconsistent views that are later almost impossible to reconcile [20].

Let us expand the previous example into a second example. Suppose that a materialized view \( V \) of \( S_1 \), considered as a primary copy, is replicated in data mart \( S_2 \). Now, additional synchronization is needed so that the updates issued by the two data source nodes and the updates of \( V \) issued by \( S_1 \) execute in the same order for all replicas in \( S_1 \) and \( S_2 \).

Thus, a central problem is the design of algorithms that maintain replica’s consistency in lazy master replicated databases, while minimizing the performance degradation due to the synchronization of refresh transactions. Considerable attention has been given to the maintenance of replicas’ consistency. First, many papers addressed this problem in the context of lazy group replicated systems, which require the reconciliation of updates coming from multiple primary copies [1, 15, 18, 30, 33]. Some papers have proposed to use weaker consistency criterias that depend on the application semantics. For instance, in the OSCAR system [10], each node processes the updates received from master nodes according to a specific weak-consistency method that is associated with each secondary copy. However, their proposition does not yield the same notion of consistency as ours. In [2, 3, 31], authors propose some weak consistency criterias based on time and space, e.g., a replica should be refreshed after a time interval or after 10 updates on a primary copy. There, the concern is not anymore on fast refreshment and hence these solutions are not adequate to our problem. In [9], the authors give conditions over the placement of secondary and primary copies into sites under which a lazy master replicated database can be guaranteed to be globally serializable (which corresponds to our notion of consistency). However, they do not propose any refreshment algorithm for the cases that do not match their conditions, such as our two previous examples. Finally, some synchronization algorithms have been proposed and implemented in commercial systems, such as Digital’s Reliable Transaction Router [4], where the refreshment of all secondary copies of a primary copy is done in a distributed transaction. However, to the best of our knowledge, these algorithms do not assure replica consistency in cases like our second above example.

This paper makes three important contributions with respect to the central problem mentioned before. First, we analyze different types of configurations of a lazy master replicated system. A configuration represents the topology of distribution of primary and secondary copies across the system nodes. It is a directed graph where a directed arc connects a node \( N \) to a node \( N' \) if and only if \( N \) holds a primary copy of some secondary copy in \( N' \). We formally define the notion of correct refreshment algorithm that assures database consistency. Then, for each type of configuration, we define sufficient conditions that must be satisfied by a refreshment algorithm in order to be correct. Our results generalize already published results such as [9].
As a second contribution, we propose a simple and general refreshment algorithm, which is proved to be correct for a large class of acyclic configurations (including for instance, the two previous examples). We show how to implement this algorithm using system components that can be added to a regular database system. Our algorithm makes use of a reliable multicast with a known upper bound, that preserves a global FIFO order. Our algorithm also uses a deferred update propagation strategy, as offered by all commercial replicated database systems. The general principle of the algorithm is to make every refresh transaction wait a certain “deliver time” before being executed.

As a third contribution, we propose two main optimizations to this algorithm. First, using our correctness results on configurations types, we provide a static characterization of nodes that do not need to wait. Second, we give an optimized version of the algorithm that uses an immediate update propagation strategy, as defined in [28]. We give a performance evaluation based on simulation that demonstrates the value of this optimization by showing that it significantly improves the freshness of secondary copies.

This paper is a significantly extended version of [29]. The extensions are the following. First, we provide all the proofs of the propositions defining our correctness criteria. Second, we extend our performance evaluation by measuring freshness and the impact of update transactions aborts for up to 8 master nodes. Third, we expand the related work section.

The rest of this paper is structured as follows. Section 2 introduces our lazy master replication framework, and the typology of configurations. Section 3 defines the correctness criteria for each type of configuration. Section 4 describes our refreshment algorithm, how to incorporate it in the system architecture of nodes, and proves its correctness. Section 5 presents our two main optimizations. Section 6 introduces our simulation environment and presents our performance evaluation. Section 7 discusses some related work. Finally, Section 8 concludes.

2. Lazy master replicated databases

We define a (relational) lazy replicated database system as a set of \( n \) interconnected database systems, henceforth called nodes. Each node \( N_i \) hosts a relational database whose schema consists of a set of pairwise distinct relational schemas, whose instances are called relations. A replication scheme defines a partitioning of all relations of all nodes into partitions, called replication sets. A replication set is a set of relations having the same schema, henceforth called replica copies.\(^3\) We define a special class of replicated systems, called lazy master, which is our framework.

2.1. Ownership

Following [18], the ownership defines the node capabilities for updating replica copies. In a replication set, there is a single updatable replica copy, called primary copy (denoted by a capital letter), and all the other relations are called secondary copies (denoted by lower-case letters). We assume that a node never holds the primary copy and a secondary copy of the same replication set. We distinguish between three kinds of nodes in a lazy master replicated system.
Definition 2.1 (Types of nodes).

1. A node $M$ is said to be a master node iff: $\forall m \in M$ $m$ is a primary copy.
2. A node $S$ is said to be a slave node iff: $\forall s \in S$ $s$ is a secondary copy of a primary copy of some master node.
3. A node $MS$ is said to be a master/slave node iff: $\exists ms$ and $ms' \in MS$, such that $ms$ is a primary copy and $ms'$ is a secondary copy.

Finally, we define the following slave and master dependencies between nodes. A node $M$ is said to be a master node of a node $S$ iff there exists a secondary copy $r$ in $S$ of a primary copy $R$ in $M$. We also say that $S$ is a slave node of $M$.

2.2. Configurations

Slave dependencies define a DAG, called configuration.

Definition 2.2 (Configuration). A configuration of a replicated system is defined by a directed graph, whose nodes are the nodes of the replicated system, and there is a directed are from a node $N$ to a node $N'$ iff $N'$ is a slave node of $N$. Node $N$ is said to be a predecessor of $N'$.

In the following, we distinguish different types of configurations. Intuitively, to each configuration will correspond a correctness criterion to guarantee database consistency. In the figures illustrating the configurations, we use integers to represent nodes in order to avoid confusion with the names of the relations that are displayed as annotation of nodes.

Definition 2.3 (1 master-per-slave configuration). An acyclic configuration in which each node has at most one predecessor is said to be a $1$-master-per-slave configuration.

![Figure 1](image.png)

This configuration, illustrated in figure 1(a), corresponds to a “data dissemination” scheme whereby a set of primary copies of a master or master/slave node is disseminated towards a set of nodes. It characterizes for instance the case of several data marts built over a centralized corporate data warehouse.
Definition 2.4 (1slave-per-master configuration). An acyclic configuration in which each node has at most one successor is said to be a 1slave-per-master configuration.

This configuration, illustrated in figure 1(b), corresponds to what is often called a “data consolidation” scheme, whereby primary copies coming from different nodes are replicated into a single node. It characterizes for instance a configuration wherein a data warehouse node (or even, an operational data store node) holds a set of materialized views defined over a set of relations stored by source nodes. In this context, replicating the source relations in the data warehouse node has two main benefits. First, one can take advantage of the replication mechanism to propagate changes from the source towards the data warehouse. Second, it assures the self-maintainability of all materialized views in the data warehouse, thereby avoiding the problems mentioned in [35].

Definition 2.5 (bowtie configuration). An acyclic configuration in which there exist two distinct replicas $X_1$ and $X_2$ and four distinct nodes $M_1$, $M_2$, $S_1$ and $S_2$ such that (i) $M_1$ holds the primary copy of $X_1$ and $M_2$ the primary copy of $X_2$, and (ii) both $S_1$ and $S_2$ hold secondary copies of both $X_1$ and $X_2$.

Such configuration, illustrated in figure 1(c), generalizes the two previous configurations by enabling arbitrary slave dependencies between nodes. This configuration characterizes, for instance, the case of several data marts built over several data sources. The benefits of a replication mechanism are the same as for a data consolidation configuration.

Definition 2.6 (triangular configuration). An acyclic configuration in which there exist three distinct nodes $M$, $MS$ and $S$ such that (i) $MS$ is a successor of $M$, and (ii) $S$ is a successor of both $M$ and $MS$, is said to be a triangular configuration. Nodes $M$, $MS$ and $S$ are said to form a triangle.

This configuration, illustrated in figure 2 (a), slightly generalizes the two first configurations by enabling a master/slave node to play an added intermediate role between a master node and a slave node. This configuration was also considered in [9].

\[ \text{Figure 2. Examples of configurations.} \]
Definition 2.7 (materialized view). A primary copy of a master/slave node MS which is defined as the result of the query over a set of secondary copies of MS is called a materialized view.

Definition 2.8 (view triangular configuration). A derived configuration in which all the primary copies hold by any node MS of any triangle are materialized views of local secondary copies, is said to be a view triangular configuration.

This configuration, illustrated in figure 2(b), characterizes, for instance, the case of two independent data marts defined over the same data warehouse in which one of the data mart replicates some materialized view of the other data mart. Although they overlap, the bowtie and the view triangular configurations are incomparable (none is included into the other).

2.3. Transaction model

The transaction model defines the properties of the transactions that access the replica copies at each node. Moreover, we assume that once a transaction is submitted for execution to a local transaction manager at a node, all conflicts are handled by the local concurrency control protocol, in such a way that serializability of local transactions is ensured.

We focus on three types of transactions that read or write replica copies: update transactions, refresh transactions and queries. All these transactions access only local data.

An update transaction is a local user transaction (i.e., executing on a single node) that updates a set of primary copies. Updates performed by an update transaction \( T \) are made visible to other transactions only after \( T \)'s commitment. We denote \( T_{R_1, R_2} \) an update transaction that updates primary copies \( R_1, R_2 \). We assume that no user transaction can update a materialized view.

A refresh transaction associated with an update transaction \( T \) and a node \( N \), is composed by the serial sequence of write operations performed by \( T \) on the replica copies hold by \( N \). We denote \( RT_{r_1, r_2} \) a refresh transaction that updates secondary copies \( r_1, r_2 \). Finally, a query transaction, noted \( Q \), consists of a sequence of read operations on replica copies.

2.4. Propagation

The propagation parameter defines “when” the updates to a primary copy must be multicast towards the nodes storing its secondary copies. The multicast is assumed to be reliable and to preserve the global FIFO order [22]: the updates are received by the involved nodes in the order they have been multicast by the node having the primary copy.

Following [28], we focus on two types of propagation: deferred and immediate. When using a deferred propagation strategy, the sequence of operations of each refresh transaction associated with an update transaction \( T \) is multicast to the appropriate nodes within a single message \( M \), after the commitment of \( T \). When using an immediate propagation, each operation of a refresh transaction associated with an update transaction \( T \) is immediately multicast inside a message \( m \), without waiting for the commitment of \( T \).
2.5. Refreshment

The refreshment algorithm defines: (i) the triggering parameter i.e., when a refresh transaction is started, and (ii) the ordering parameter i.e., the commit order of refresh transactions.

We consider three triggering modes: deferred, immediate and wait. The combination of a propagation parameter and a triggering mode determines a specific update propagation strategy. With a deferred-immediate strategy, a refresh transaction \( RT \) is submitted for execution as soon as the corresponding message \( M \) is received by the node. With an immediate-immediate strategy, a refresh transaction \( RT \) is started as soon as the first message \( m \) corresponding to the first operation of \( RT \) is received. Finally, with an immediate-wait strategy, a refresh transaction \( RT \) is submitted for execution only after the last message \( m \) corresponding to the commitment of the update transaction associated with \( RT \) is received.

3. Correctness criteria

In this section, we first formally define the notion of a correct refreshment algorithm, which characterizes a refreshment algorithm that does not allow inconsistent states in a lazy master replicated system. Then for each type of configuration introduced in Section 2, we provide criteria that must be satisfied by a refreshment algorithm in order to be correct.

We now introduce useful preliminary definitions similar to those used in [19] in order to define the notion of a consistent replicated database state. We do not consider node failures, which are out of the scope of this paper. As a first requirement, we impose that any committed update on a primary copy must be eventually reflected by all its secondary copies.

**Definition 3.1 (Validity).** A refreshment algorithm used in a lazy master replicated system is said valid iff any node that has a copy of a primary copy updated by a committed transaction \( T \) is guaranteed to commit the refresh transaction \( RT \) associated with \( T \).

**Definition 3.2 (Observable State).** Let \( N \) be any node of a lazy master replicated system, the observable state of node \( N \) at local time \( t \) is the instance of the local data that reflects all and only those update and refresh transactions committed before \( t \) at node \( N \).

In the next definitions, we assume a global clock so that we can refer to global times in defining the notion of consistent global database state. The global clock is used for concept definition only. We shall also use the notation \( I_t[N](Q) \) to denote the result of a query transaction \( Q \) run at node \( N \) at time \( t \).

**Definition 3.3 Quiescent State.** A lazy master replicated database system is in a quiescent state at a global time \( t \) if all local update transactions submitted before \( t \) have either aborted or committed, and all the refresh transactions associated with the committed update transactions have committed.

**Definition 3.4 Consistent Observable State.** Let \( N \) be any node of a lazy master replicated system \( D \). Let \( t \) be any global time at which a quiescent state of \( D \) is reached. An observable
state of node \( \mathcal{N} \) at time \( t_\mathcal{N} \leq t \) is said to be consistent iff for any node \( \mathcal{N}' \) holding a non-empty set \( X \) of replica copies hold by \( \mathcal{N} \) and for any query transaction \( Q \) over \( X \), there exists some time \( t_{\mathcal{N}'} \leq t \) such that \( I_{t_\mathcal{N}}[\mathcal{N}](Q) = I_{t_{\mathcal{N}'}}[\mathcal{N}'][Q] \).

**Definition 3.5 Correct Refreshment Algorithm for a node \( \mathcal{N} \).** A refreshment algorithm used in a lazy master replicated system \( \mathcal{D} \), is said to be correct for a node \( \mathcal{N} \) of \( \mathcal{D} \) iff it is valid and for any quiescent state reached at time \( t \), any observable state of \( \mathcal{N} \) at time \( t_{\mathcal{N}} \leq t \) is consistent.

**Definition 3.6 Correct Refreshment Algorithm.** A refreshment algorithm used in a lazy master replicated system \( \mathcal{D} \), is said to be correct iff it is correct for any node \( \mathcal{N} \) of \( \mathcal{D} \).

In the following, we define correctness criteria for acyclic configurations that are sufficient conditions on the refreshment algorithm to guarantee that it is correct.

### 3.1. Global FIFO ordering

For 1master-per-slave configurations, inconsistencies may arise if slaves can commit their refresh transactions in an order different from their corresponding update transactions. Although in 1slave-per-master configurations, every primary copy has a single associated secondary copy, the same case of inconsistency could occur between the primary and secondary copies. The following correctness criterion prevents this situation.

**Definition 3.7 Global FIFO order.** Let \( T_1 \) and \( T_2 \) be two update transactions committed by the same master or master/slave node \( \mathcal{M} \). If \( \mathcal{M} \) commits \( T_1 \) before \( T_2 \), then at every node having a copy of a primary copy updated by \( T_1 \), a refresh transaction associated with \( T_2 \) can only commit after the refresh transaction associated with \( T_1 \).

**Proposition 3.1.** If a lazy master replicated system \( \mathcal{D} \) has an acyclic configuration which is neither a bowtie nor a triangular configuration, and \( \mathcal{D} \) uses a valid refreshment algorithm meeting the global FIFO order criterion, then this refreshment algorithm is correct.

See the proof in the Section 9.1 of the appendix. A similar result was shown in [9] using serializability theory.

### 3.2. Total ordering

Global FIFO ordering is not sufficient to guarantee the correctness of refreshment for bowtie configurations. Consider the example in figure 1(c). Two master nodes, node 1 and node 2, store relations \( R(A) \) and \( S(B) \), respectively. The updates performed on \( R \) by some transaction \( T_R \): insert \( R(A : a) \), are multicast towards nodes 3 and 4. In the same way, the updates performed on \( S \) by some transaction \( T_S \): insert \( S(B : b) \), are multicast towards nodes 3 and 4. With the correctness criterion of Proposition 3.1, there is no ordering among the commits of refresh transactions \( R_T \) and \( R_T \) associated with \( T_R \) and \( T_S \). Therefore, it
might happen that \(RT_i\) commits before \(RT_s\) at node 3 and in a reverse order at node 4. In which case, a simple query transaction \(Q\) that computes \((R - S)\) could return an empty result at node 4, which is impossible at node 3. The following criterion requires that \(RT_i\) and \(RT_s\) commit in the same order at nodes 3 and 4.

**Definition 3.8** (Total order). Let \(T_1\) and \(T_2\) be two committed update transactions. If two nodes commit both the associated refresh transactions \(RT_1\) and \(RT_2\), they both commit \(RT_1\) and \(RT_2\) in the same order.

**Proposition 3.2.** *If a lazy master replicated system \(D\) that has a bowtie configuration but not a triangular configuration, uses a valid refreshment algorithm meeting the global FIFO order and the total order criteria, then this refreshment algorithm is correct.*

See the proof in the Section 9.2 of the appendix.

### 3.3. Master/slave induced ordering

We first extend the model presented in Section 2 to deal with materialized views as follows. From now on, we shall consider that in a master/slave node \(MS\) having a materialized view, say \(V(s_1)\), any refresh transaction of \(s_1\) is understood to encapsulate the update of some virtual copy \(\hat{V}\). The actual replica copies \(V\) and \(v\) are then handled as if they were secondary copies of \(\hat{V}\). Hence, we consider that the update of the virtual copy \(\hat{V}\) is associated with:

- at node \(MS\), a refresh transaction of \(V\), noted \(RT_V\),
- \(\mathbf{\forall}\) at any node \(S\) having a secondary copy \(v\), a refresh transaction of \(V\) noted \(RT_V\).

With this new modeling in mind, consider the example of figure 2(b). Let \(V(A)\) be the materialized view defined from the secondary copy \(s_1\). Suppose that at the initial time \(t_0\) of the system, the instance of \(V(A)\) is: \(\{V(A : 8)\}\) and the instance of \(S(B)\) is: \(\{S(B : 9)\}\). Suppose that we have two update transactions \(T_s\) and \(T_V\), running at nodes 1 and 2 respectively: \(T_s\): [delete \(S(B : 9)\); insert \(S(B : 6)\), and \(T_V\): [if exists \(S(B : x)\) and \(x \leq 7\) then delete \(V(A : 8)\); insert \(V(A : 5)\)]. Finally, suppose that we have the query transaction \(Q\) over \(V\) and \(S\): \(Q\): [if exists \(V(A : x)\) and \(S(B : Y)\) and \(y < x\) then \(bool = true\) else \(bool = false\)], where \(bool\) is a variable local to \(Q\).

Now, a possible execution is the following. First, \(T_s\) commits at node 1 and its update is multicast towards nodes 2 and 3. Then, \(RT_{T_s}\) commits at node 2. At this point of time, say \(t_1\), the instance of \(s_1\) is \(\{s_1(B : 6)\}\). Then the update transaction \(T_V\) commits, afterwards the refresh transaction \(RT_V\) commits. The instance of \(V\) is \(\{V(A : 5)\}\). Then at node 3, \(RT_V\) commits (the instances of \(v\) and \(s_2\) are \(\{v(A : 5)\}\) and \(\{s_2(B : 9)\}\)), and finally, \(RT_{T_s}\) commits (the instances of \(v\) and \(s_2\) are \(\{v(A : 5)\}\) and \(\{s_2(B : 6)\}\)). A quiescent state is reached at this point of time, say \(t_2\).

However, there exists an inconsistent observable state. Suppose that \(Q\) executes at time \(t_1\) on node 2. Then, \(Q\) will return a value \(true\) for \(bool\). However, for any time between \(t_0\) and \(t_2\), the execution of \(Q\) on node 3 will return a value \(false\) for \(bool\), which contradicts our definition of consistency.
The following criterion imposes that the commit order of refresh transactions must reflect the commit order at the master/slave node.

**Definition 3.9 (Master/slave induced order).** If $MS$ is a node holding a secondary copy $s_1$ and a materialized view $V$, then any node $N_i$, $i > 1$, having secondary copies $s_i$ and $v_i$ must commit its refresh transactions $RT_{s_i}$ and $RT_{v_i}$ in the same order as $RT_{V}$ and $RT_{s_1}$ commit at $MS$.

**Proposition 3.3.** *If a lazy master replicated system D that has a view triangular configuration but not a bowtie configuration, uses a valid refreshment algorithm meeting the global FIFO order and the master/slave induced order criteria then this refreshment algorithm is correct.*

See the proof in the Section 9.3 of the appendix.

As said before, a configuration can be both a bowtie and a view triangular configuration. In this case, the criteria for both configurations must be enforced.

**Proposition 3.4.** *If a lazy master replicated system D having both a view triangular configuration and a bowtie configuration, uses a valid refreshment algorithm meeting the global FIFO order, the master/slave induced order and the total order criteria, then this refreshment algorithm is correct.*

See the proof in the Section 9.3 of the appendix.

### 4. Refreshment algorithm

We start this section by presenting the system architecture assumed by our algorithms. Then, we present our refreshment algorithm that uses a deferred update propagation strategy and prove its correctness. Finally we discuss the rationale for our algorithm.

#### 4.1. System architecture of nodes

To maintain the autonomy of each node, we assume that four components are added to a regular database system, that includes a transaction manager and a query processor, in order to support a lazy master replication scheme. Figure 3 illustrates these components for a node having both primary and secondary copies. The first component, called *Replication Module*, is itself composed of three sub-components: a Log Monitor, a Propagator and a Receiver. The second component, called *Refresher*, implements a refreshment strategy. The third component, called *Deliverer*, manages the submission of refresh transactions to the local transaction manager. Finally, the last component, called *Network Interface*, is used to propagate and receive update messages (for simplicity, it is not portrayed on figure 3). We now detail the functionality of these components.

We assume that the *Network Interface* provides a global FIFO reliable multicast [22] with a known upper bound [13]: messages multicast by a same node are received in the order
they have been multicast. We also assume that each node has a local clock. For fairness reasons, clocks are assumed to have a bounded drift and to be $\varepsilon$ synchronized. This means that the difference between any two correct clocks is not higher than the precision $\varepsilon$.

The Log Monitor uses log sniffing [23, 30] to extract the changes to a primary copy by continuously reading the content of a local History Log (noted $H$). We safely assume (see Chap. 9 of [17]) that a log record contains all the information we need such as the timestamp of a committed update transaction, and other relevant attributes that will be presented in the next section. Each committed update transaction $T$ has a timestamp (henceforth denoted $C$), which corresponds to the real time value at $T$’s commitment time. When the log monitor finds a write operation on a primary copy, it reads the corresponding log record from $H$ and writes it into a stable storage, called Input Log, that is used by the Propagator. We do not deal with conflicts between the write operations on the History Log and the read operations performed by the Log Monitor.

The Receiver implements update message reception. Messages coming from different masters or master/slaves are received and stored into a Reception Log. The receiver then reads messages from this log and stores them in FIFO pending queues. We denote $Max$, the upper bound of the time needed to multicast a message from a node and insert it into a pending queue at a receiving node. A node $N$ has as many pending queues $q_1, \ldots, q_n$ as masters or master/slaves nodes from which $N$ has a secondary copy. The contents of these queues form the input to the Refresher.

The Propagator implements the propagation of update messages constructed from the Log Monitor. Such messages are first written into the Input Log. The propagator then continuously reads the Input Log and propagates messages through the network interface.

The Refresher implements the refreshment algorithm. First, it reads the contents of the pending queues, and based on its refreshment parameters, submits refresh transactions by inserting them into a running queue. The running queue contains all ordered refresh transactions not yet entirely executed.

Finally, the Deliverer submits refresh transactions to the local transaction manager. It reads the content of the running queue in a FIFO order and submits each write operation as
part of a refresh transaction to the local transaction manager. The local transaction manager ensures serializability of local transactions. Moreover, it executes the operations requested by the refresh transactions according to the submission order given by the Deliverer.

4.2. Refreshment algorithm

As described in Section 2, the refreshment algorithm has a triggering and an ordering parameters. In this section, we present the refreshment algorithm in the case of a deferred-immediate update propagation strategy (i.e., using an immediate triggering), and focus on the ordering parameter.

The principle of the refreshment algorithm is the following. A refresh transaction RT is committed at a slave or master/slave node (1) once all its write operations have been done, (2) according to the order given by the timestamp \( C \) of its associated update transaction, and (3) at the earliest, at real time \( C + \text{Max} + \varepsilon \), which is called the deliver time, noted deliver time. Therefore, as clocks are assumed to be \( \varepsilon \) synchronized, the effects of updates on secondary copies follow the same chronological order in which their corresponding primary copies were updated.

Deferred-Immediate Refresher
input: pending queues \( q_1 \ldots q_n \)
output: running queue
variables:
\( \text{curr}_M, \text{new}_M \): messages from pending queues; 
\( \text{timer} \): local reverse timer whose state is either active or inactive;
begin
\( \text{timer.state} = \text{inactive}; \)
\( \text{curr}_M = \text{new}_M = \emptyset; \)
repeat
on message arrival or change of timer’s state to inactive do
Step 1:
\( \text{new}_M \leftarrow \text{message with min } C \text{ among top messages of } q_1, q_n; \)
Step 2:
if \( \text{new}_M \neq \text{curr}_M \) then
\( \text{curr}_M \leftarrow \text{new}_M; \)
calculate deliver time(\( \text{curr}_M \));
\( \text{timer.value} \leftarrow \text{deliver time(\( \text{curr}_M \))} - \text{local time} \)
\( \text{timer.state} \leftarrow \text{active}; \)
endif
on timer.value = 0 do
Step 3:
write \( \text{curr}_M \) into running queue;
dequeue \( \text{curr}_M \) from its pending queue;
\( \text{timer.state} \leftarrow \text{inactive}; \)
for ever
end

Figure 4. Deferred-immediate refreshment algorithm.

We now detail the algorithm given in figure 4. Each element of a pending queue is a message that contains: a sequence of write operations corresponding to a refresh transaction \( RT \), and the timestamp \( C \) of the update transaction associated with \( RT \). Since messages
successively multicast by a same node are received in that order by the destination nodes, in any pending queue, messages are stored according to their multicast order (or commitment order of their associated update transactions).

Initially, all pending queues are empty, and \( \text{curr}_M \) and \( \text{new}_M \) are empty too. Upon arrival of a new message \( M \) into some pending queue signaled by an event, the Refresher assigns variable \( \text{new}_M \) with the message that has the smallest \( C \) among all messages in the top of all pending queues. If two messages have equal timestamps, one is selected according to the master or master/slave identification priorities. This corresponds to Step 1 of the algorithm. Then, the Refresher compares \( \text{new}_M \) with the currently hold message \( \text{curr}_M \). If the timestamp of \( \text{new}_M \) is smaller than the timestamp of \( \text{curr}_M \), then \( \text{curr}_M \) gets the value of \( \text{new}_M \). Its deliver time is then calculated, and a local reverse timer is set with value \( \text{deliver.time} - \text{local.time} \). This concludes Step 2 of the algorithm. Finally, whenever the timer expires its time, signaled by an event, the Refresher writes \( \text{curr}_M \) into the running queue and dequeues it from its pending queue. Each message of the running queue will yield a different refresh transaction. If an update message takes \( \text{Max} \) time to reach a pending queue, it can be processed immediately by the Refresher.

4.3. Refreshment algorithm correctness

We first show that the refreshment algorithm is valid for any acceptable configuration. A configuration is said acceptable iff (i) it is acyclic, and (ii) if it is a triangular configuration, then it is a view triangular configuration.

**Lemma 4.1.** The Deferred-immediate refreshment algorithm is valid for any acceptable configuration.

**Lemma 4.2 (Chronological order).** The Deferred-immediate refreshment algorithm ensures for any acceptable configuration that, if \( T_1 \) and \( T_2 \) are any two update transactions committed respectively at global times \( t_1 \) and \( t_2 \) then:
- if \( t_2 - t_1 > \varepsilon \), the timestamps \( C_2 \) for \( T_2 \) and \( C_1 \) for \( T_1 \) meet \( C_2 > C_1 \).
- any node that commits both associated refresh transactions \( RT_1 \) and \( RT_2 \), commits them in the order given by \( C_1 \) and \( C_2 \).

**Lemma 4.3.** The Deferred-immediate refreshment algorithm satisfies the global FIFO order criterion for any acceptable configuration.

**Lemma 4.4.** The Deferred-immediate refreshment algorithm satisfies the total order criterion for any acceptable configuration.

**Lemma 4.5.** The Deferred-immediate refreshment algorithm satisfies the master/slave induced order criterion for any acceptable configuration.

From the previous lemmas and propositions, we have:

**Theorem 4.1.** The Deferred-immediate refreshment algorithm is correct for any acceptable configuration.
4.4. Discussion

A key aspect of our algorithm is to rely on the upper bound $\text{Max}$ on the transmission time of a message by the global FIFO reliable multicast. Therefore, it is essential to have a value of $\text{Max}$ that is not overestimated. The computation of $\text{Max}$ resorts to scheduling theory (e.g., see [34]). It usually takes into account four kinds of parameters. First, there is the global reliable multicast algorithm itself (see for instance [22]). Second, are the characteristics of the messages to multicast (e.g. arrival laws, size). For instance, in [14], an estimation of $\text{Max}$ is given for sporadic message arrivals. Third, are the failures to be tolerated by the multicast algorithm, and last are the services used by the multicast algorithm (e.g. medium access protocol). It is also possible to compute an upper bound $\text{Max}_i$ for each type $i$ of message to multicast. In that case, the refreshment algorithm at node $N$ waits until $\max_{i \in J} \text{Max}_i$, where $J$ is the set of message types that can be received by node $N$.

Thus, an accurate estimation of $\text{Max}$ depends on an accurate knowledge of the above parameters. However, accurate values of the application dependent parameters can be obtained in performance sensitive replicated database applications. For instance, in the case of data warehouse applications that have strong requirements on freshness, certain characteristics of message can be derived from the characteristics of the operational data sources (usually, transaction processing systems). Furthermore, in a given application, the variations in the transactional workload of the data sources can often be predicted.

In summary, the approach taken by our refreshment algorithm to enforce a total order over an algorithm that implements a global FIFO reliable multicast trades the use of a worst case multicast time at the benefit of reducing the number of messages exchanged on the network. This is a well known tradeoff. This solution brings simplicity and ease of implementation.

5. Optimizations of the refreshment

In this section, we present two main optimizations for the refreshment algorithm presented in Section 4. First, we show that for some configurations, the deliver time of a refresh transaction needs not to include the upper bound ($\text{Max}$) of the network and the clock precision ($\varepsilon$), thereby considerably reducing the waiting time of a refresh transaction at a slave or master/slave node. Second, we show that without sacrificing correctness, the principle of our refreshment algorithm can be combined with immediate update propagation strategies, as they were presented in [28]. Performance measurements, reported in Section 6, will demonstrate the value of this optimization.

5.1. Eliminating the deliver time

There are cases where the waiting time associated with the deliver time of a refresh transaction can be eliminated. For instance, consider a multinational investment bank that has traders in several cities, including New York, London, and Tokyo. These traders update a local database of positions (securities held and quantity), which is replicated using a lazy master scheme (each site is a master for securities of that site) into a central site that warehouses the common database for all traders. The common database is necessary in order
for risk management software to put limits on what can be traded and to support an internal market. A trade will be the purchase of a basket of securities belonging to several sites. In this context, a delay in the arrival of a trade notification may expose the bank to excessive risk. Thus, the time needed to propagate updates from a local site to the common database must be very small (e.g., below a few seconds).

This scheme is a 1slave-per-master configuration, which only requires a global FIFO order to ensure the correctness of its refreshment algorithm (see proposition 3.1). Since, we assume a reliable FIFO multicast network, there is no need for a refresh transaction to wait at a slave node before being executed. More generally, given an arbitrary acceptable configuration, the following proposition characterizes those slave nodes that can process refresh transactions without waiting for their deliver time.

**Proposition 5.1.** Let N a node of a lazy master replicated system D. If for any node N’ of D, X being the set of common replicas between N and N’, we have:

- cardinal (X) ≤ 1, or
- ∀X1, X2, ∈ X, the primary copies of X1 and X2 are hold by the same node, then any valid refreshment algorithm meeting the global FIFO order criterion is correct for node N.

Figure 5 illustrates a configuration meeting Proposition 5.1 for any node of the configuration. For instance, let us consider node 1. The set of replicas hold by both node 1 and node 2 is the singleton r. The set of replicas hold by both node 1 and node 3 is the set r, s, whose primaries are hold by node 1. Node 1 holds no replica in common with another node except node 2 and node 3. Hence node 1 meets Proposition 5.1.

**Proof:** We proceed by contradiction assuming that an inconsistent state of N can be observed. There is a time t at which a quiescent state of D is reached. There exist a node N’ ∈ D, a non-empty set X of replicas hold by both N and N’, a time tN ≤ t and a query transaction Q over X such that, for any time t’N ≤ t, we have I_{tN}[N](Q) ≠ I_{t’N}[N’](Q).

We distinguish two cases:

- **Case 1:** cardinal (X) = 1. Let X1 be the unique replica of X and N’” be the node holding the primary copy of X1. By definition, a valid refreshment protocol ensures that any

![Figure 5](image-url)
node having a secondary copy of \( X \), commits the refresh transaction associated with a committed transaction updating \( X \) at node \( N' \). The global FIFO order criterion forces nodes \( N \) and \( N' \) to commit the refresh transactions in the same order as their associated update transactions have committed at node \( N' \). Hence, a contradiction.

- **Case 2**: \( X \) contains at least two distinct replicas. In the previous case, we have shown that any secondary copy commits refresh transactions according to the commit order of their associated update transactions at the primary copy. It follows that the different results obtained by a query transaction \( Q \) at nodes \( N \) and \( N' \) come from a misordering of two transactions commits. Let \( X_1 \) and \( X_2 \) the two distinct replicas of \( X \) such that node \( N \) commits an update/refreshment of \( X_1 \) before an update/refreshment of \( X_2 \) and node \( N' \) commits first the update/refreshment of \( X_2 \) and then the update/refreshment of \( X_1 \). By assumption, the primary copies of \( X_1 \) and \( X_2 \) are held by the same node \( N'' \). The global FIFO order criterion forces nodes \( N \) and \( N' \) to reproduce the same commit order as node \( N'' \). Hence, a contradiction.

From an implementation point of view, the same refreshment algorithm runs at each node. The behavior of the refreshment algorithm regarding the need to wait or not, is simply conditioned by a local variable. Thus, when the configuration changes, only the value of the variable of each node can possibly change.

### 5.2. Immediate propagation

We assume that the Propagator and the Receiver both implement an immediate propagation strategy as specified in [28], and we focus here on the Refresher. Due to space limitations, we only present the immediate-immediate refreshment algorithm. We have chosen the immediate-immediate version because it is the one that provides the best performance compared with deferred-immediate, as indicated in [28].

#### 5.2.1. Immediate-immediate refreshment.

We detail the algorithm of figure 6. Unlike deferred-immediate refreshment, each element of a pending queue is a message \( m \) that carries an operation \( o \) of some refresh transaction, and a timestamp \( C \). Initially, all pending queues are empty. Upon arrival of a new message \( m \) in some pending queue, signaled by an event, the Refresher reads the message and if \( m \) does not correspond to a commit, inserts it into the running queue. Thus, any operation carried by \( m \) other than commit can be immediately submitted for execution to the local transaction manager. If \( m \) contains a commit operation then \( new_m \) is assigned with the commit message that has the smallest \( C \) among all messages in the top of all pending queues. Then, \( new_m \) is compared with \( curr_m \). If \( new_m \) has a smallest timestamp than \( curr_m \), then \( curr_m \) is assigned with \( new_m \). Afterwards, the Refresher calculates the deliver time for \( curr_m \), and timer is set as in the deferred-immediate case. Finally, when the timer expires, the Refresher writes \( curr_m \) into the running queue, dequeues it from its pending queue, sets the timer to inactive and re-executes Step 1.
5.2.2. Algorithm correctness. Like the deferred-immediate refreshment algorithm, the immediate-immediate algorithm enforces refresh transactions to commit in the order of their associated update transactions. Thus, the proofs of correctness for any acceptable configuration are the same for both refreshment algorithms.

6. Performance evaluation

In this section, we summarize the main performance gains obtained by an immediate-immediate refreshment algorithm against a deferred-immediate one. More extensive performance results are reported in [28]. We use a simulation environment that reflects as much as possible a real replication context. We focus on a bowtie configuration which requires the use of a \( \text{Max} + \epsilon \) deliver time, as explained in Section 5.2. However, once we have fixed the time spent to reliably multicast a message, we can safely run our experiments with a single slave and several masters.

Our simulation environment is composed of Master, Network, Slave modules and a database server. The Master module implements all relevant capabilities of a master node such as log monitoring and message propagation. The Network module implements the most significant factors that may impact our update propagation strategies such as the delay to
reliably multicast a message. The Slave module implements the most relevant components of the slave node architecture such as Receiver, Refresher and Deliverer. In addition, for performance evaluation purposes, we add the Query component in the slave module, which implements the execution of queries that read replicated data. Since, we do not consider node failures, the reception log is not taken into account. Finally, a database server is used to implement refresh transactions and query execution.

Our environment is implemented on a Sun Solaris workstation using Java/JDBC as the underlying programming language. We use sockets for inter-process communication and Oracle 7.3 to implement refresh transaction execution and query processing. For simulation purposes, each write operation corresponds to an UPDATE command that is submitted to the server for execution.

6.1. Performance model

The metrics used to compare the two refreshment algorithms is given by the freshness of secondary copies at the slave node. More formally, given a replica X, which is either a secondary or a primary copy, we define \( n(X, t) \) as the number of committed update transactions on X at global time \( t \). We assume that update transactions can have different sizes but their occurrence is uniformly distributed over time. Using this assumption, we define the degree of freshness of a secondary copy \( r \) at global time \( t \) as:

\[
f(r, t) = n(r, t) / n(R, t);
\]

Therefore, a degree of freshness close to 0 means bad data freshness while close to 1 means excellent. The mean degree of freshness of \( r \) at a global time \( T \) is defined as:

\[
\text{mean}_f = \frac{1}{T} \int_0^T f(r, t) \, dt
\]

Table 1. Performance parameters.

</tbody>
</table>

We now present the main parameters for our experiments summarized in Table 1. We assume that the mean time interval between update transactions, noted \( \lambda_t \), as reflected by the history log of each master, is bursty. Updates are done on the same attribute (noted attr) of a different tuple. We focus on dense update transactions, i.e., transactions with a small time interval between each two writes. We define two types of update transactions.
Small update transactions have size 5 (i.e., 5 write operations), while long transactions have size 50. We define four scenarios in which the proportion of long transactions, noted \( ltr \), is set respectively to 0, 30, 60, and 100. Thus, in a scenario where \( ltr = 30 \), 30% of the executed update transactions are long. Finally, we define an abort transaction ratio, noted \( abr \), of 0, 5%, 10%, 20%, that corresponds to the percentage of transactions that abort in an experiment. Furthermore, we assume that a transaction abort always occurs after half of its execution. For instance \( abr = 10\% \) means that 10% of the update transactions abort after the execution of half of their write operations.

Network delay is calculated by \( \delta + t \), where \( \delta \) is the time between the insertion of a message in the input queue of the Network module and the multicast of the message by that module, and \( t \) is the reliable multicast time of a message until its insertion in the pending queue of the Refresher. Concerning the value of \( t \) used in our experiments, we have a short message multicast time, noted \( t_{\text{short}} \), which represents the time needed to reliably multicast a single log record. In addition, we consider that the time spent to reliably multicast a sequence of log records is linearly proportional to the number of log records it carries. The network overhead delay, \( \delta \), takes into account the time spent in the input queue of the Network, it is implicitly modeled by the system overhead to read from and write to sockets. The Total propagation time (noted \( t_p \)) is the time spent to reliably multicast all log records associated with a given transaction. Thus, if \( n \) represents the size of the transaction with immediate propagation, we have \( t_p = n \times (\delta + t_{\text{short}}) \), while with deferred propagation, we have \( t_p = (\delta + n \times t_{\text{short}}) \). Network contention occurs when \( \delta \) increases due to the increase of network traffic. In this situation, the delay introduced by \( \delta \) may impact the total propagation time, especially with immediate propagation. Finally, when \( ltr > 0 \), the value of Max is calculated using the maximum time spent to reliably multicast a long transaction \( (50 * t_{\text{short}}) \). On the other hand, when \( ltr = 0 \), the value of Max is calculated using the maximum time spent to reliably multicast a short transaction \( (50 * t_{\text{short}}) \).

The refresh transaction execution time is influenced by the existence of possible conflicting queries that read secondary copies at the slave node. Therefore, we need to model queries. We assume that the mean time interval between queries is low, and the number of data items read is small (fixed to 5). We fix a 50% conflict rate for each secondary copy, which means that each refresh transaction updates 50% of the tuples of each secondary copy that are read by a query.

To measure the mean degree of freshness, we use the following variables. Each time an update transaction commits at a master, variable \( \text{version}_{\text{master}} \) for that master, is incremented. Similarly, each time a refresh transaction commits at the slave, variable \( \text{version}_{\text{slave}} \), is incremented. Whenever a query conflicts with a refresh transaction we measure the degree of freshness.

### 6.2. Experiments

We present three experiments. The results are average values obtained from the execution of 40 update transactions. The first experiment shows the mean degree of freshness obtained for the bursty workload. The second experiment studies the impact on freshness when update transactions abort. In the third experiment, we verify the freshness improvement of each strategy when the network delay to propagate a message increases.
We now summarize and discuss the major observations of our experiments. As depicted in figure 7, when $ltr = 0$ (short transactions), the mean degree of freshness is already impacted because on average, $\lambda_t < t_p$. Therefore, during $T_i$’s update propagation, $T_{i+1}, T_{i+2} \cdots T_{i+n}$ may be committed. Notice that even with the increase of network contention, immediate-immediate yields a better mean degree of freshness. With 2, 4, and 8 masters, the results of immediate-immediate are much better than those of deferred-immediate, as $ltr$ increases (see figure 8). For instance, with 4 masters with $ltr = 30$, the mean degree of freshness is 0.62 for immediate-immediate and 0.32 for deferred-immediate. With 6 masters and $ltr = 60$, the mean degree of freshness is 0.55 for immediate-immediate, and 0.31 for deferred-immediate. In fact, immediate-immediate always yields the best mean degree of freshness even with network contention due to the parallelism of log monitoring, propagation, and refreshment.

Figure 7. Bursty workload—response time.

Figure 8. Bursty workload—mean degree of freshness.
With *immediate-immediate*, the mean query response time may be seriously impacted because each time a query conflicts with a refresh transaction, it may be blocked during a long period of time since the propagation time may be added to the refresh transaction execution time. When $\lambda_0 \gg \lambda_1$, the probability of conflicts is quite high. There, the network delay to propagate each operation has an important role and the higher its value, the higher are the query response times in conflict situations. However, we verified that the use of a multiversion protocol on the slave node may significantly reduces query response times, without a significant decrease in the mean degree of freshness.

The *abort* of an update transaction with *immediate-immediate* does not impact the mean degree of freshness since the delay introduced to undo a refresh transaction is insignificant compared to the propagation time. As shown in figure 9, for $l_{tr} = 0$ and various values of $abr$ (5, 10, 20), the decrease of freshness introduced by update transactions that abort with *immediate-immediate* is insignificant. In the worst case, it achieves 0.2. This behavior is the same for other values of $l_{tr}$ (30, 60, 100).

Finally, the improvements brought by *immediate-immediate* are more significant when the network delay to propagate a single operation augments. Figure 10 compares the freshness results obtained when $\delta = 100$ ms and $\delta = 20$ ms. For instance, when $\delta = 20$ and $l_{tr} = 100$ *immediate-immediate* improves 1.1 times better than *deferred-immediate* and when $\delta = 100$, *immediate-immediate* improves 5 times better. This clearly shows the advantages of having tasks being executed in parallel.
7. Related work

Apart from the work cited in Section 1, the closest work to ours is in [9]. The authors show that for any strongly acyclic configuration a refreshment algorithm which enforces a global FIFO ordering, guarantees a global serializability property, which is similar to our notion of correction. Their result is analogous to our Proposition 3.1. They also propose an algorithm, which assigns, when it is possible, a site to each primary copy so that the resulting configuration is strongly acyclic. However, no algorithm is provided to refresh secondary copies in the cases of non strongly acyclic configurations.

In [6] the authors propose two new lazy update protocols (DAG(WT) and DAG(T)) that ensure serializability for acyclic configurations and imposes a much weaker requirement on data placement than [9]. Close to our approach, the DAG(T) protocol is based on timestamp ordering. Notice, however that there timestamp is based on logical clocks.

Much work has been devoted to the maintenance of integrity constraints in federated or distributed databases, including the case of replicated databases [7, 11, 19, 21]. These papers propose algorithms and protocols to prevent the violation of certain kind of integrity constraints by local transactions. However, their techniques are not concerned with the consistent refreshment of replicas.

Table 2 summarizes the two major lazy replication schemes and their basic parameters. Replication scheme A corresponds to lazy replication where all replica copies are updatable (update anywhere). In this case, there is group ownership of the replicas. The common
update propagation strategy for this scheme is deferred-immediate. However, conflicts may occur if two or more nodes update the same replica copy. Policies for conflict detection and resolution [16, 5] can be based on timestamp ordering, node priority and other strategies. The problem with conflict resolution is that during a certain period of time, the database may be in an inconsistent state.

For instance, in [30], the authors describe a lazy group replication scheme in which the update propagation protocol applies updates to replicated data in their arrival order, possibly restoring inconsistencies when arrivals violate the timestamp ordering of transactions. Notice that conflicts cannot be avoided but their detection may happen earlier by using an immediate propagation.

The timestamp message delivery protocol in [15] implements eventual delivery for a lazy group replication scheme [18]. It uses periodic exchange of messages between pairs of servers that propagate messages to distinct groups of master nodes. At each master node incoming messages are stored in a history log (as initially proposed in [23]) and later delivered to the application in a defined order. Eventual delivery is not appropriate in our framework since we are interested in improving data freshness.

Replication scheme B is the focus of our work. There are several refreshment strategies for this replication scheme. With on demand refreshment, each time a query is submitted for execution, secondary copies that are read by the query are refreshed by executing all the refresh transactions that have been received. Therefore, a delay may be introduced in query response time. When group refresh is used, refresh transactions are executed in groups according to the application's freshness requirements. With the periodic approach, refreshment is triggered at fixed intervals. At refreshment time, all received refresh transactions are executed. Finally, with periodic propagation, changes performed by update transactions are stored in the master and propagated periodically towards the slaves. Immediate propagation may be used with all refreshment strategies.

The stability and convergence of replication schemes A and B are compared in [18] through an analytical model. The authors show that scheme A has unstable behavior as the workload scales up and that using scheme B reduces the problem. They introduce several concepts such as lazy master and ownership which we use. They also explore the use of mobility.

The goal of epidemic algorithms [33] is to ensure that all replicas of a single data item converge to the same value in a lazy group replication scheme. Updates are executed locally at any node. Later, nodes communicate to exchange up-to-date information. In our approach, updates are propagated from each primary copy towards its secondary copies.

Formal concepts for specifying coherency conditions in a replicated distributed database have been introduced in [12]. The authors focus on a deferred-immediate update propagation strategy and propose concepts for computing a measure of relaxation. Their concept of version is closely related to our notion of freshness.

Oracle 7.3 [24] implements event-driven replication. Triggers on the master tables make copies of changes to data for replication purposes, storing the required change information in tables called queues that are periodically propagated. Sybase 10 replication server replicates transactions, not tables, across nodes in the network. The Log Transfer Manager implements
log monitoring like our approach. However, these systems do not implement immediate propagation and there is no multi-queue scheme for refreshment.

8. Conclusion

In a lazy master replicated system, a transaction can commit after updating one replica copy (primary copy) at some node. The updates are propagated towards the other replicas (secondary copies), and these replicas are refreshed in separate refresh transactions.

We proposed refreshment algorithms which address the central problem of maintaining replicas’ consistency. An observer of a set of replicas at some node never observes a state which is never seen by another observer of the same set of replicas at another node.

This paper has three major contributions. Our first contribution is a formal definition of (i) the notion of correct refreshment algorithm and (ii) correctness criteria for any acceptable configuration.

Our second contribution is an algorithm meeting these correctness criteria for any acceptable configuration. This algorithm can be easily implemented over an existing database system. It is based on a deferred update propagation, and it delays the execution of a refresh transaction until its deliver time.

Our third contribution concerns optimizations of the refreshment algorithm in order to improve the data freshness. With the first optimization, we characterized the nodes that do not need to wait. The second optimization uses immediate-immediate update propagation strategy. This strategy allows parallelism between the propagation of updates and the execution of the associated refresh transactions.

Finally, our performance evaluation shows that the immediate-immediate strategy always yields the best mean degree of freshness for a bursty workload.

9. Appendix

In this appendix, we detail the proofs of the four propositions given respectively in Sections 3.1, 3.2 and 3.3. These propositions define correctness criteria of a refreshment algorithm for different acyclic configurations. Section 9.1 deals with an acyclic configuration which is neither a bowtie nor a triangular configuration. Section 9.2 deals with a bowtie configuration which is not a triangular one. Finally, Section 9.3 deals with a view triangular configuration.

9.1. Correctness criterion for an acyclic configuration which is neither a bowtie nor a triangular configuration

As said in Section 3.1, the correctness criterion for an acyclic configuration which is neither a bowtie nor a triangular configuration, is the following one:

**Proposition 3.1.** If a lazy master replicated system $D$ has an acyclic configuration which is neither a bowtie nor a triangular configuration and $D$ uses a valid refreshment algorithm meeting the global FIFO order criterion, then this refreshment algorithm is correct.
To prove this proposition, we proceed by step. We first establish three preliminary lemmas. The first one deals with each replica copy taken individually. The second one shows that if the correctness criterion is violated, then necessarily there are two replicas such their updates have been committed in a different order by two nodes. The last lemma enounces all the possible cases for two replicas shared by two nodes. Finally, we prove the proposition.

We now enounce the first lemma. We consider each replica copy individually and show that at each replica copy, updates are committed in the order they have been committed at the primary copy.

**Lemma 9.1.** In a lazy master replicated system $D$, using a valid refreshment protocol meeting the global FIFO order criterion, let $t$ be any global time at which a quiescent state of $D$ is reached. For any node $N$, for any replica copy $X$ hold by $N$, for any node $N'$ holding $X$, for any query transaction $Q$ over the only replica copy $X$, for any time $t_N \leq t$, there exists a time $t_{N'} \leq t$ such that $I_{t_N}[N](Q) = I_{t_{N'}}[N'][Q]$. 

**Proof:** We proceed by contradiction. We assume that there is a time $t_N \leq t$ such that for any time $t_{N'} \leq t$ we have: $I_{t_N}[N](Q) \neq I_{t_{N'}}[N'][Q]$. We distinguish two cases:

- either $N$ holds the primary copy of $X$. Hence the query over $X$ at node $N$ reflects all the update transactions committed before $t_N$. According to the validity property, all the associated refresh transactions will be committed at nodes having a secondary copy of $X$. Moreover the global FIFO order criterion forces the refresh transactions to be committed in the order of their associated update transactions. Hence a contradiction.
- or $N$ holds a secondary copy of $X$. If $N'$ holds the primary copy of $X$, by analogy with the previous case, we obtain a contradiction. If now $N'$ holds a secondary copy of $X$, then by the validity property and by the global FIFO order criterion, all the nodes having a secondary copy of $X$ must reflect all the updates transactions committed before $t_N$ and in the order they have been committed on the primary copy of $X$. Hence a contradiction.

We now show that if a query transaction over a common set $X$ of replicas gives different results at two nodes $N$ and $N'$, then there exist two replicas $X_1$ and $X_2$ in $X$ such that their updates have been committed in a different order by nodes $N$ and $N'$.

**Lemma 9.2.** In a lazy master replicated system $D$, using a valid refreshment protocol meeting the global FIFO order criterion, let $t$ be any global time at which a quiescent state of $D$ is reached. If there are nodes $N$ and $N'$, a non-empty set $X$ of replica copies hold by $N$ and $N'$, a query transaction $Q$ over $X$, a time $t_N \leq t$ such that for any time $t_{N'} \leq t$ we have: $I_{t_N}[N](Q) \neq I_{t_{N'}}[N'][Q]$, then there are two distinct replicas $X_1$ and $X_2$ in $X$ such that their updates/refreshes have been committed in a different order by nodes $N$ and $N'$.

**Proof:** We assume that there are nodes $N$ and $N'$, a non-empty set $X$ of replica copies hold by $N$ and $N'$, a query transaction $Q$ over $X$, a time $t_N \leq t$ such that for any time $t_{N'} \leq t$ we have: $I_{t_N}[N](Q) \neq I_{t_{N'}}[N'][Q]$. From lemma 9.1, this is impossible if the cardinal of $X$ is one. Hence we assume that $X$ contains at least two distinct replicas. If the results of $Q$ over $X$
differ at nodes $N$ and $N'$, it means that the transactions having updated/refreshed the replicas in $X$ have committed in a different order at nodes $N$ and $N'$. Hence there are two distinct replicas $X_1$ and $X_2$ in $X$, with $X_1 \neq X_2$, such that node $N$ commits an update/refresh of $X_1$ before an update/refresh of $X_2$, and node $N'$ commits an update/refresh of $X_2$ before an update/refresh of $X_1$. Hence the lemma.

We now consider all the possible cases for two nodes of an acyclic configuration, holding both at least two replica copies.

**Lemma 9.3.** In an acyclic configuration of a lazy master replicated system $D$, for any two distinct nodes $N$ and $N'$ holding both two distinct replica copies $X_1$ and $X_2$, the only possible cases are:

1. either $N$ has the primary copies of both $X_1$ and $X_2$; $N'$ is a slave of $N$;
2. or $N'$ has the primary copies of both $X_1$ and $X_2$; $N$ is a slave of $N'$;
3. or both $N$ and $N'$ have secondary copies of both $X_1$ and $X_2$.
4. or $N$ has the primary copy of $X_1$ and a secondary copy of $X_2$; $N'$ has secondary copies of both $X_1$ and $X_2$.
5. or $N'$ has the primary copy of $X_1$ and a secondary copy of $X_2$; $N$ has secondary copies of both $X_1$ and $X_2$.
6. or $N$ has the primary copy of $X_2$ and a secondary copy of $X_1$; $N'$ has secondary copies of both $X_1$ and $X_2$.
7. or $N'$ has the primary copy of $X_2$ and a secondary copy of $X_1$; $N$ has secondary copies of both $X_1$ and $X_2$.

**Proof:** We consider all the possible cases for two distinct nodes $N$ and $N'$ holding both a replica copy of $X_1$ and a replica copy of $X_2$ with $X_1 \neq X_2$. We have 16 possible cases for the attribution of the primary/secondary copy of $X_1$ and $X_2$ to $N$ and $N'$. Each case can be coded with four bits with the following meaning:

- the first bit is one if $N$ holds the primary copy of $X_1$ and zero otherwise;
- the second bit is one if $N$ holds the primary copy of $X_2$ and zero otherwise;
- the third bit is one if $N'$ holds the primary copy of $X_1$ and zero otherwise;
- the fourth bit is one if $N'$ holds the primary copy of $X_2$ and zero otherwise;

Among them, seven are impossible, because for any replica, only one node holds the primary copy. Hence, the impossible cases are $1010$, $1110$, $1011$, $1111$, $0101$, $0111$, $1101$. We now prove that the cases $1001$ and $0110$ are impossible. Let us consider the case $1001$ where $N$ holds the primary copy of $X_1$ and $N'$ holds the primary copy of $X_2$. We then have $N$ is a slave of $N'$ (because of $X_2$) and $N'$ is a slave of $N$ (because of $X_1$). The configuration is then cyclic: a contradiction with our assumption. By analogy, the case $0110$ is impossible.

Hence there are $16 - 7 - 2 = 7$ only possible cases, which are given in the lemma.

We can now prove the proposition given at the beginning of Section 9.1.
Proof of Proposition 3.1: We proceed by contradiction. There exist a node $N$ and a node $N'$ with $N \neq N'$ such that $X$ the set of replica hold by both $N$ and $N'$ is non empty, there exist a query transaction $Q$ over $X$ and a time $t_N \leq t$ such that $\forall t'_N \leq t$, we have $I_{t_N}[N](Q) \neq I_{t_N}[N'](Q)$. From Lemma 9.2, there exist two distinct replicas $X_1$ and $X_2$ in $X$ such that their updates have been committed in a different order by nodes $N$ and $N'$.

We will now consider all the cases given by Lemma 9.3.

1. either $N$ has the primary copies of both $X_1$ and $X_2$; $N'$ is a slave of $N$; The global FIFO order criterion enforces $N'$ to commit the refresh transactions in the order their associated update transactions have been committed by $N$. Hence a contradiction.
2. or $N'$ has the primary copies of both $X_1$ and $X_2$; $N$ is a slave of $N'$; This is the symmetrical case of the previous one. We then obtain a contradiction.
3. or both $N$ and $N'$ have secondary copies of both $X_1$ and $X_2$. Notice that this case is impossible in a 1slave-per-master configuration (both $N$ and $N'$ would be slave of the node holding the primary copy of $X_1$). Let $N_1$ be the node holding the primary copy of $X_1$. Let $N_2$ be the node holding the primary copy of $X_2$. Since the configuration is not a bowtie configuration, we necessarily have $N_1 = N_2$. The global FIFO order criterion enforces both $N$ and $N'$ to commit the refresh transactions in the order their associated update transactions have been committed by $N_1 = N_2$. Hence a contradiction.
4. or $N$ has the primary copy of $X_1$ and a secondary copy of $X_2$; $N'$ has secondary copies of both $X_1$ and $X_2$. There exists a node $N_2$ holding the primary copy of $X_2$ such that $N$ and $N'$ are slaves of $N_2$ and $N'$ is slave of $N$. This case and all the following ones would lead to a triangular configuration. Hence, a contradiction.

9.2. Correctness criterion for an acyclic configuration which is a bowtie configuration but not a triangular one

As said in Section 3.2, the correctness criterion for an acyclic configuration which is a bowtie configuration but not a triangular one, is the following one:

Proposition 3.2. If a lazy master replicated system $D$ that has a bowtie configuration but not a triangular configuration, uses a valid refreshment algorithm meeting the global FIFO order and the total order criteria, then this refreshment algorithm is correct.

Proof of Proposition 3.2: We proceed by contradiction. There exist a node $N$ and a node $N'$ with $N \neq N'$ such that $X$ the set of replica hold by both $N$ and $N'$ is non empty, there exist a query program $P$ over $X$ and a time $t_N \leq t$ such that $\forall t'_N \leq t$, we have $I_{t_N}[N](P) \neq I_{t_N}[N'](P)$. From Lemma 9.2, there exist two distinct replicas $X_1$ and $X_2$ in $X$ such that their updates have been committed in a different order by nodes $N$ and $N'$.

We will now consider all the cases given by Lemma 9.3.

1. either $N$ has the primary copies of both $X_1$ and $X_2$; $N'$ is a slave of $N$; The global FIFO order criterion enforces $N'$ to commit the refresh transactions in the order their associated update transactions have been committed by $N$. Hence a contradiction.
2. or $N'$ has the primary copies of both $X_1$ and $X_2$; $N$ is a slave of $N'$; This is the symmetrical case of the previous one. We then obtain a contradiction.
3. or both $N$ and $N'$ have secondary copies of both $X_1$ and $X_2$. Let $N1$ be the node holding the primary copy of $X_1$. Let $N2$ be the node holding the primary copy of $X_2$. The total order criterion enforces both $N$ and $N'$ to commit the refresh transactions on $X_1$ and $X_2$ in the same order. Hence, a contradiction.

4. or $N$ has the primary copy of $X_1$ and a secondary copy of $X_2$; $N'$ has secondary copies of both $X_1$ and $X_2$. There exists a node $N2$ holding the primary copy of $X_2$ such that $N$ and $N'$ are slaves of $N2$ and $N'$ is slave of $N$. This case and all the following ones would lead to a triangular configuration. Hence, a contradiction.

9.3. Correctness criterion for an acyclic configuration which is a view triangular one

As said in Section 3.3, the correctness criterion for an acyclic configuration which is a view triangular one but not a bowtie configuration, is the following one:

**Proposition 3.3.** If a lazy master replicated system $D$ that has a view triangular configuration but not a bowtie configuration, uses a valid refreshment algorithm meeting the global FIFO order and the master/slave induced order criteria, then this refreshment algorithm is correct.

**Proof of Proposition 3.3:** We proceed by contradiction. There exist a node $N$ and a node $N'$ with $N = N'$ such that $X$ the set of replica hold by both $N$ and $N'$ is non empty, there exist a query program $P$ over $X$ and a time $t_N < t$ such that $\forall t_{N'} < t$, we have $I_{t_N}[N](P) \neq I_{t_{N'}}[N'](P)$. From Lemma 9.2, there exist two distinct replicas $X_1$ and $X_2$ in $X$ such that their updates have been committed in a different order by nodes $N$ and $N'$.

We will now consider all the cases given by Lemma 9.3.

1. either $N$ has the primary copies of both $X_1$ and $X_2$; $N'$ is a slave of $N$; The global FIFO order criterion enforces $N'$ to commit the refresh transactions in the order their associated update transactions have been committed by $N$. Hence a contradiction.

2. or $N'$ has the primary copies of both $X_1$ and $X_2$; $N$ is a slave of $N'$; This is the symmetrical case of the previous one. We then obtain a contradiction.

3. or both $N$ and $N'$ have secondary copies of both $X_1$ and $X_2$. Let $N1$ be the node holding the primary copy of $X_1$. Let $N2$ be the node holding the primary copy of $X_2$. Since the configuration is not a bowtie configuration, we necessarily have $N1 = N2$. The global FIFO order criterion forces both $N$ and $N'$ to commit the refresh transactions on $X_1$ and $X_2$ in the order their associated update transactions have been committed by $N1 = N2$. Hence, a contradiction.

4. or $N$ has the primary copy of $X_1$ and a secondary copy of $X_2$; $N'$ has secondary copies of both $X_1$ and $X_2$. There exists a node $N2$ holding the primary copy of $X_2$ such that $N$ and $N'$ are slaves of $N2$ and $N'$ is slave of $N$. As the configuration is a view triangular one, $X_1$ is a materialized view from local secondary copies. The master/slave induced order criterion enforces nodes $N$ and $N'$ to commit the refresh transactions of $X_1$ and $X_2$ in the same order. Hence, a contradiction. \qed
If now, the lazy master replicated system has both a view triangular configuration and a bowtie configuration, then the correctness criterion becomes:

Proposition 3.4. If a lazy master replicated system $D$ having both a view triangular configuration and a bowtie configuration, uses a valid refreshment algorithm meeting the global FIFO order, the master/slave induced order and the total order criteria then this refreshment algorithm is correct.

Proof of Proposition 3.4: We proceed by contradiction. There exist a node $N$ and a node $N'$ with $N \neq N'$ such that $X$ the set of replica hold by both $N$ and $N'$ is non empty, there exist a query program $P$ over $X$ and a time $t_N \leq t$ such that $\forall t_N \leq t$, we have $I_{t_N}[N](Q) \neq I_{t_N}[N'][P]$. From Lemma 9.2, there exist two distinct replicas $X_1$ and $X_2$ in $X$ such that their updates have been committed in a different order by nodes $N$ and $N'$.

We will now consider all the cases given by Lemma 9.3.

1. either $N$ has the primary copies of both $X_1$ and $X_2$; $N'$ is a slave of $N'$; The global FIFO order criterion forces $N'$ to commit the refresh transactions in the order their associated update transactions have been committed by $N$. Hence a contradiction.
2. or $N'$ has the primary copies of both $X_1$ and $X_2$; $N$ is a slave of $N'$; This is the symmetrical case of the previous one. We then obtain a contradiction.
3. or both $N$ and $N'$ have secondary copies of both $X_1$ and $X_2$. Let $N_1$ be the node holding the primary copy of $X_1$. Let $N_2$ be the node holding the primary copy of $X_2$. The total order criterion forces both $N$ and $N'$ to commit the refresh transactions on $X_1$ and $X_2$ in the same order. Hence, a contradiction.
4. or $N$ has the primary copy of $X_1$ and a secondary copy of $X_2$; $N'$ has secondary copies of both $X_1$ and $X_2$. There exists a node $N_2$ holding the primary copy of $X_2$ such that $N$ and $N'$ are slaves of $N_2$ and $N'$ is slave of $N$. As the configuration is a view triangular one, $X_1$ is a materialized view from local secondary copies. The master/slave induced order criterion enforces nodes $N$ and $N'$ to commit the refresh transactions of $X_1$ and $X_2$ in the same order. Hence, a contradiction.
5. this case and all the following ones are symmetrical to the previous one. □

Notes

1. From now on, we suppose that replicas are relations.
2. This frequent situation typically arises when no corporate data warehouse has been set up between data sources and data marts. Quite often, each data mart, no matter how focused, ends up with views of the business that overlap and conflict with views held by other data marts (e.g., sales and inventory data marts). Hence, the same relations can be replicated in both data marts [20].
3. A replication set can be reduced to a singleton if there exists a single copy of a relation in the replicated system.
4. called coherence index.

Abstract. In a database cluster, preventive replication can provide strong consistency without the limitations of synchronous replication. In this paper, we present a full solution for preventive replication that supports multi-master and partial configurations, where databases are partially replicated at different nodes. To increase transaction throughput, we propose an optimization that eliminates delay at the expense of a few transaction aborts and we introduce concurrent replica refreshment. We describe large-scale experimentation of our algorithm based on our RepDB* prototype (http://www.sciences.univ-nantes.fr./lina/ATLAS/RepDB) over a cluster of 64 nodes running the PostgreSQL DBMS. Our experimental results using the TPC-C Benchmark show that the proposed approach yields excellent scale-up and speed-up.

Keywords: database cluster, partial replication, preventive replication, strong consistency, TPC-C benchmarking

1. Introduction

High-performance and high-availability of database management have been traditionally achieved with parallel database systems [23], implemented on tightly-coupled multiprocessors. Parallel data processing is then obtained by partitioning and replicating the data across the multiprocessor nodes in order to divide processing. Although quite effective, this solution requires the database system to have full control over the data and is expensive in terms of software and hardware.

Clusters of PC servers now provide a cost-effective alternative to tightly-coupled multiprocessors. They have been used successfully by, for example, Web search engines using high-volume server farms (e.g., Google). However, search engines are typically read-intensive, which makes it easier to exploit parallelism. Cluster systems can make new businesses such as Application Service Providers (ASP) economically viable. In the ASP model, customers’ applications and databases (including data and DBMS) are hosted at

*Work partially funded by the MDP2P project of the ACI “Masses de Données” of the French Ministry of Research.
the provider site and need be available, typically through the Internet, as efficiently as if they were local to the customer site. Notice that due to autonomy, it is possible that the DBMS at each node are heterogeneous. To improve performance, applications and data can be replicated at different nodes so that users can be served by any of the nodes depending on the current load [1]. This arrangement also provides high-availability since, in the event of a node failure, other nodes can still do the work. However, managing data replication in the ASP context is far more difficult than in Web search engines since applications can be update-intensive and both applications and databases must remain autonomous. The solution of using a parallel DBMS is not appropriate as it is expensive, requires heavy migration to the parallel DBMS and hurts database autonomy.

In this paper, we consider a database cluster with similar nodes, each having one or more processors, main memory (RAM) and disk. Similar to multiprocessors, various cluster system architectures are possible: shared-disk, shared-cache and shared-nothing [23]. Shared-disk and shared-cache require a special interconnect that provide a shared space to all nodes with provision for cache coherence using either hardware or software. Shared-nothing (or distributed memory) is the only architecture that supports our autonomy requirements without the additional cost of a special interconnect. Furthermore, shared-nothing can scale up to very large configurations. Thus, we strive to exploit a shared-nothing architecture.

The major problem of data replication is to manage the consistency of the replicas in the presence of updates [6]. The basic solution in distributed systems that enforces strong replica consistency is synchronous (or eager) replication (typically using the Read-One-Write All—ROW A protocol [11]). Whenever a transaction updates a replica, all other replicas are updated inside the same distributed transaction. Therefore, the mutual consistency of the replicas is enforced. However, synchronous replication is not appropriate for a database cluster for two main reasons. First, all the nodes would have to homogeneously implement the ROWA protocol inside their local transaction manager, thus violating DBMS autonomy. Second, the atomic commitment of the distributed transaction should rely on the two-phase commit (2PC) protocol [11] which is known to be blocking (i.e. does not deal well with nodes’ failures) and has poor scale up.

A better solution that scales up is lazy replication [14], where a transaction can commit after updating a replica, called primary copy, at some node, called master node. After the transaction commits, the other replicas, called secondary copies, are updated in separate refresh transactions at slave nodes. Lazy replication allows for different replication configurations [12]. A useful configuration is lazy master where there is only one primary copy. Although it relaxes the property of mutual consistency, strong consistency is assured. However, it hurts availability since the failure of the master node prevents the replica to be updated. A more general configuration is (lazy) multi-master where the same primary copy, called a multi-owner copy, may be stored at and updated by different master nodes, called multi-owner nodes. The advantage of multi-master is high-availability and high-performance since replicas can be updated in parallel at different nodes. However, conflicting updates of the same primary copy at different nodes can introduce replica incoherence.

Preventive replication [13] is an asynchronous solution that enforces strong consistency. Instead of using atomic broadcast, as in synchronous group-based replication [9], preventive replication uses First-In First-Out (FIFO) reliable multicast which is a weaker constraint.
It works as follows. Each incoming transaction is submitted, via a load balancer, to the best node of the cluster. Each transaction \( T \) is associated with a chronological timestamp value \( C \), and is multicast to all other nodes where there is a replica. At each node, a delay time \( d \) is introduced before starting the execution of \( T \). This delay corresponds to the upper bound of the time needed to multicast a message. When the delay expires, all transactions that may have committed before \( C \) are guaranteed to be received and executed before \( T \), following the timestamp chronological order (i.e. total order). Hence, this approach prevents conflicts and enforces consistency. Its implementation over a cluster of 8 nodes showed good performance [13].

However, the original proposal has two main limitations. First, it assumes that databases are fully replicated across all cluster nodes and thus propagates each transaction to each cluster node. This makes it unsuitable for supporting large databases and heavy workloads on large cluster configurations. Second, it has performance limitations since transactions are performed one after the other, and must endure waiting delays before starting. Thus, refreshment is a potential bottleneck, in particular, in the case of bursty workloads where the arrival rates of transactions are high at times. This paper addresses these important limitations. It is based on the solution initially proposed in [4] with significant extensions regarding replication configurations, concurrency management, proofs of algorithms and performance evaluation.

In this paper, we provide support for partial replication, where databases are partially replicated at different nodes. Unlike full replication, partial replication can increase access locality and reduce the number of messages for propagating updates to replicas. To increase transaction throughput, we propose a refreshment algorithm that potentially eliminates the delay time, and we introduce concurrent replica refreshment. We describe the implementation of our algorithm in our RepDB\(^\ast\) prototype [19] over a cluster of 64 nodes running the PostgreSQL DBMS. Our experimental results using the TPC-C Benchmark show that it yields excellent scale-up and speed-up.

The rest of the paper is organized as follows. Section 2 introduces the global architecture for processing user requests against applications into the cluster system. Section 3 defines the basic concepts for fully and partial replication. Section 4 describes preventive refreshment for partially replication, including the algorithm and architecture. Section 5 proposes some important optimizations to the refreshment algorithm that improves transaction throughput. Section 6 describes our validation and experimental results. Section 7 discusses related work. Section 8 concludes.

2. Database cluster architecture

In this section, we introduce the architecture for processing user requests against applications into the cluster system and discuss our general solutions for placing applications, submitting transactions and managing replicas. Therefore, the replication layer is identified together with all other general components.

In this paper, we exploit a shared-nothing architecture. This is the only architecture that allows sufficient node autonomy without the additional cost of special interconnects. In our shared-nothing architecture, each cluster node is composed of five layers (see
When a user request arrives at the cluster, traditionally through an access node, it is sent randomly to a cluster node $i$. There is no significant data processing at the access node, avoiding bottlenecks. Within that cluster node, the user is authenticated and authorized through the Request Router, available at each node, using a multi-threaded global user directory service. Notice that user requests are managed completely asynchronously. Next, if a request is accepted, then the Request Router chooses a node $j$, to submit the request. The choice of node $j$ involves selecting all nodes in which the required application is available, and, among these nodes, the node with the lightest load. Therefore, eventually $i$ may be equal to $j$. The Request Router then routes the user request to an application node using a traditional load balancing algorithm.

Notice, however, that the database accessed by the user request may be placed at another node $k$ since applications and databases are both replicated and not every node hosts a database system. In this case, the choice regarding node $k$ will depend on the cluster configuration and the database load at each node.

A node load is computed by a current load monitor available at each node. For each node, the load monitor periodically computes application and transaction loads using traditional load balancing strategies. For each type of load, it establishes a load grade and multicasts the grades to all the other nodes. A high grade corresponds to a high load. Therefore, the Request Router chooses the best node for a specific request using the node grades (light node is better as discussed below).

The Application Manager is the layer that manages application instantiation and execution using an application server provider. Within an application, each time a transaction is to be executed, the Transaction Load Balancer layer is invoked which triggers transaction
execution at the best node, using the load grades available at each node. The “best” node is defined as the one with lighter transaction load. The Transaction Load Balancer ensures that each transaction execution obeys the ACID (atomicity, consistency, isolation, durability) properties [14], and then signals to the Application Manager to commit or abort the transaction.

The Replication Manager layer manages access to replicated data and assures strong consistency in such a way that transactions that update replicated data are executed in the same serial order at each node. We employ data replication because it provides database access parallelism for applications. Our preventive replication approach avoids conflicts at the expense of a forced waiting time for transactions, which is negligible due to the fast cluster network system.

3. Replication model

In this section, we define all the terms and concepts of lazy replication for fully and partially replicated databases necessary to understand our solutions. Then, we present the consistency criteria for the three types of configurations: Lazy-Master, Multi-master and Partially replicated.

3.1. Configurations

We assume that a replica is an entire relational table. Given a table $R$, we may have three kinds of copies: primary, secondary and multi-master. A primary copy, denoted by $R$, is stored at a master node where it can be updated while a secondary copy, denoted by $r_i$, is stored at one or more slave nodes $i$ in read-only mode. A multi-master copy, denoted by $R_i$, is a primary copy that may be stored at several multi-master nodes $i$. Figure 2 shows various replication configurations, using two tables $R$ and $S$.

Figure 2(a) shows a bowtie (lazy master) configuration where there are only primary copies and secondary copies. This configuration is useful to speed-up the response times of read-only queries through the slave nodes, which do not manage the update transaction load. However, availability is limited since, in the case of a master node failure, its primary copies can no longer be updated.

![Figure 2. Replication configurations.](image-url)
Figure 2(b) shows a fully replicated configuration. In this configuration, all nodes manage the update transaction load because whenever $R$ or $S$ is updated at one node, all other copies need be updated asynchronously at the other nodes. Thus, only the read-only query loads are different at each node. Since all the nodes perform all the transactions, load balancing is easy because all the nodes have the same load (when the specification of the nodes is homogeneous) and availability is high because any node can replace any other node in case of failure.

Figures 2(c) and (d) illustrate partially replicated configurations where all kinds of copies may be stored at any node. For instance, in figure 2(c), node $N_1$ carries the multi-master copy $R_1$ and the primary copy $S$, node $N_2$ carries the multi-master copy $R_2$ and the secondary copy $s_1$, node $N_3$ carries the multi-master copy $R_3$, and node $N_4$ carries the secondary copy $s_2$. Compared with full replication, only some of the nodes are affected by the updates on a multi-master copy (only those that hold common multi-master copies). Therefore, transactions do not have to be multicast to all the nodes. Thus, the nodes and the network are less loaded and the overhead for refreshing replicas is significantly reduced.

With partial replication a transaction $T$ may be composed of a sequence of read and write operations followed by a commit (as produced by the SQL statement in figure 3) that updates multi-master copies. This is more general than in [13] where only write operations are considered. We define a refresh transaction as the sequence of write operations of a transaction, as written in the Log History. In addition, a refreshment algorithm is the algorithm that manages, asynchronously, the updates on a set of multi-master and secondary copies once one of the multi-master (or primary) copies is updated by $T$ for a given configuration.

Given a transaction $T$ received in the database cluster, there is an origin node chosen by the load balancer that triggers refreshment, and a set of target nodes that carries replicas involved with $T$. For simplicity, the origin node is also considered a target node. For instance, in figure 2(b) whenever node $N_1$ receives a transaction that updates $R_1$, then $N_1$ is the origin node and $N_1$, $N_2$, $N_3$ and $N_4$ are the target nodes. In figure 2(c), whenever $N_3$ receives a transaction that updates $R_3$, then the origin node is $N_3$ and the target nodes are $N_1$, $N_2$ and $N_3$.

To refresh multi-master copies in the case of full replication, it is sufficient to multicast the incoming transactions to all target nodes. But in the case of partial replication, even if a transaction is multicast towards all nodes, it may happen that the nodes are not able to execute it because they do not hold all the replicas necessary to execute $T$ locally. For instance, figure 2(c) allows an incoming transaction at node $N_1$, such as the one in figure 3 to read $s_1$ in order to update $R_1$. This transaction can be entirely executed at $N_1$ (to update $R_1$) and $N_2$ (to update $R_2$). However it cannot be executed at node $N_3$ (to update $R_3$) because $N_3$ does not hold the secondary copy $s_3$.

```
UPDATE R1 SET att1=value
WHERE att2 IN
(SELECT att3 FROM S)
COMMIT;
```

*Figure 3.* Incoming transaction at node $N_1$. 

because $N_3$ does not hold a copy of $S$. Thus, refreshing multi-master copies in the case of partial replication needs to take into account replica placement.

### 3.2. Consistency criteria

Informally a correct refreshment algorithm guarantees that any two nodes holding a common set of replicas, $R_1, R_2, \ldots, R_n$, must always produce the same sequence of updates on $R_1, R_2, \ldots, R_n$. For each configuration and its sub-configurations, we provide a criterion that must be satisfied by the refreshment algorithm in order to be correct. Group communication systems provide multicast services that differ in the final order in which messages are delivered at each node. We use these known orders [14] as a guide to express our correctness criteria. An example of each configuration is presented in Section 3.1.

**Lazy-Master configuration (figure 2(a)).** In Lazy-Master configurations, inconsistencies may arise if slave nodes can commit their refresh transactions in an order different than their corresponding master nodes. The following correctness criterion prevents this situation.

**Definition 3.1 (Total order).** Two refresh transactions $RT_1$ and $RT_2$ are said to be in total order if any slave node that commits $RT_1$ and $RT_2$, commits them in the same order.

**Proposition 3.1.** For any cluster configuration $C$ that meets a lazy-master configuration requirement, the refresh algorithm that $C$ uses is correct if and only if the algorithm enforces total order.

**Multi-Master configuration (Figure 2(d)).** In Multi-Master configurations, inconsistencies may arise whenever the serial execution orders of two transactions at two nodes are not equal. Therefore, transactions must be executed in the same serial order at any node. Thus, Global FIFO Ordering is not sufficient to guarantee the correctness of the refreshment algorithm. Hence the following correctness criterion is necessary:

**Definition 3.2 (Total order).** Two transactions $T_1$ and $T_2$ are said to be executed in Total Order if all multi-owner nodes that commit both $T_1$ and $T_2$ commit them in the same order.

**Proposition 3.2.** For any cluster configuration $C$ that meets a multi-master configuration requirement, the refresh algorithm that $C$ uses is correct if and only if the algorithm enforces total order.

**Partially-Replicated configurations (Figures 2(c) and (d)).** In a Partially-Replicated configuration, the inconsistency issues are similar to those found in each component sub-configuration, namely multi-master and lazy-master. That is, two transactions $T_1$ and $T_2$ must be executed in the same order at the multi-owner nodes, and, in addition, their corresponding refresh transactions $RT_1$ and $RT_2$ must commit in the same order in which the origin node commit $T_1$ and $T_2$. Therefore, the following correctness criterion prevents inconsistencies:
Proposition 3.3. If a cluster configuration C meets partially replicated configuration requirement, then the refresh algorithm that C uses is correct if and only if for each sub-configuration SC correctness is enforced (see Propositions 3.1 and 3.2).

Proposition 3.4. For any cluster configuration C that meets the partially replicated requirements, the refresh algorithm that C uses is correct if and only if the algorithm enforces total order.

4. Preventive refreshment

In this section, we first present the basic refreshment algorithm originally designed for full replication. Then we present the extension of the algorithm to manage partial replication. Afterwards we show the correctness of the algorithm for both fully and partially replicated configurations. Finally, we describe the Replication Manager architecture that implements these algorithms.

4.1. Full replication

We assume that the network interface provides global FIFO reliable multicast: messages multicast by one node are received at the multicast group nodes in the order they have been sent [7]. We denote by Max, the upper bound of the time needed to multicast a message from a node i to any other node j. It is essential to have a value of Max that is not over estimated. The computation of Max resorts to scheduling theory [22] and takes into account several parameters such as the global reliable network itself, the characteristics of the messages to multicast and the failures to be tolerated. We also assume that each node has a local clock. For fairness, clocks are assumed to have a drift and to be $\varepsilon$-synchronized. This means that the difference between any two correct clocks is not higher that $\varepsilon$ (known as the precision).

To define the refreshment algorithm, we need the formal correctness criterion presented in Section 3.2 to define strong copy consistency. Inconsistencies may arise whenever the serial orders of two transactions at two nodes are not equal. Therefore, they must be executed in the same serial order at any two nodes. Thus, global FIFO ordering is not sufficient to guarantee the correctness of the refreshment algorithm.

Each transaction is associated with a chronological timestamp value $C$. The principle of the preventive refreshment algorithm is to submit a sequence of transactions in the same chronological order at each node. Before submitting a transaction at node $i$, we must check whether there is any older transaction en route to node $i$. To accomplish this, the submission time of a new transaction at node $i$ is delayed by $\text{Max} + \varepsilon$. Thus the earliest time a transaction is submitted is $C + \text{Max} + \varepsilon$ (henceforth delivery time).

Whenever a transaction $T_i$ is to be triggered at some node $i$, node $i$ multicasts $T_i$ to all nodes 1, 2, $\ldots$, $n$, including itself. Once $T_i$ is received at some other node $j$ ($i$ may be equal to $j$), it is placed in the pending queue in FIFO order with respect to the triggering node $i$. Therefore, at each multi-master node $i$, there is a set of queues, $q_1$, $q_2$, $\ldots$, $q_n$, called pending queues, each of which corresponds to a multi-master node and is used by the
refreshment algorithm to perform chronological ordering with respect to the delivery times. Figure 4 shows part of the components necessary to run our algorithm. The Refresher reads transactions from the top of pending queues and performs chronological ordering with respect to the delivery times. Once a transaction is ordered, then the refresher writes it to the running queue in FIFO order, one after the other. Finally Deliver keeps checking top of the running queue to start transaction execution, one after the other, in the local DBMS.

Let us illustrate the algorithm by an example. Suppose we have two nodes $i$ and $j$, masters of the copy $R$. So at node $i$, there are two pending queues: $q(i)$ and $q(j)$ corresponding to multi-master nodes $i$ and $j$. $T_1$ and $T_2$ are two transactions which update $R$, respectively on node $i$ and on node $j$. Let us suppose that $\text{Max}$ is equal to 10 and $\varepsilon$ is equal to 1. So, on node $i$, we have the following sequence of execution:

- At time 10: $T_2$ arrives at node $i$ with a timestamp $C_2 = 5$
  - $q(i) = [T_2 (5)], q(j) = []$
  - $T_2$ is chosen by the Refresher to be the next transaction to perform at delivery time 16 ($5 + 10 + 1$), and the time is set to expire at time 16.

- At time 12: $T_1$ arrives from node $j$ with a timestamp $C_1 = 3$
  - $q(i) = [T_2 (5)], q(j) = [T_1 (3)]$
  - $T_1$ is chosen by the Refresher to be the next transaction to perform at delivery time 14 ($3 + 10 + 1$), and the time is re-set to expire at time 14.

- At time 14: the timeout expires and the Refresher writes $T_1$ into the running queue.
  - $q(i) = [T_2 (5)], q(j) = []$
  - $T_2$ is selected to be the next transaction to perform at delivery time 16 ($5 + 10 + 1$)

- At time 16: the timeout expires. The Refresher writes $T_2$ into the running queue.
  - $q(i) = [], q(j) = []$
Multi-Master Refresher

Input:
pending queues \( q_1, \ldots, q_n \)

Output:
running queue

Variables:
curr_T: currently selected transaction to be executed;
first_T: transaction with the lowest timestamp in the pending queue
timer: local reverse timer whose state is either active or inactive

Begin

timer.state = inactive;
curr_T = first_T = 0;

Repeat
On arrival of a new message
or when (timer.state = active and timer.value = 0) do

Step1:
first_T \leftarrow \text{message with min C among top messages of the pending queues;}

Step2:
If first_T \neq curr_T then
curr_M \leftarrow first_T;
calculate delivery_time(curr_T);
timer.value \leftarrow delivery_time(curr_T) - local_time

timer.state \leftarrow active;
end if

Step 3:
If timer.state = active and timer.value = 0 then
append curr_T to the running queue;
dequeue curr_T from its pending queue;
timer.state \leftarrow inactive;
end if
for ever
end

Figure 5. Multi-master refresher algorithm.

Although the transactions are received in wrong order with respect to their timestamps \((T_2 \text{ then } T_1)\) they are written into the running queue in chronological order according to their timestamps \((T_1 \text{ then } T_2)\). Thus, the total order is enforced even if messages are not sent in total order.

In figure 5, we can see the three steps of the algorithm used in the Refresher module. In step 1, at the reception of a new message in a pending queue, we choose the most recent message from the pending queues. In step 2, we calculate the delivery time according to the timestamp of the message and the \(\text{Max} + \varepsilon\), and then we set a local reverse timer that will expire at the delivery time. Finally, in step 3, when the timer is over, the message is submitted to the running queue for execution.
4.2. Partial replication

With partial replication, some of the target nodes may not be able to perform a transaction \( T \) because they do not hold all the copies necessary to perform the read set of \( T \) (recall the discussion on figure 3). However, the write sequence of \( T \), which corresponds to its refresh transaction, denoted by \( RT \), must be ordered using \( T \)’s timestamp value in order to ensure consistency. So \( T \) is scheduled as usual but not submitted for execution. Instead, the involved target nodes wait for the reception of the corresponding \( RT \). Then, at origin node \( i \), when the commitment of \( T \) is detected (by sniffing the DBMS’ log—see Section 4.3), the corresponding \( RT \) is produced and node \( i \) multicasts \( RT \) towards the target nodes. Upon reception of \( RT \) at a target node \( j \), the content of \( T \) (still waiting) is replaced with the content of incoming \( RT \) and \( T \) can be executed.

Let us now illustrate the algorithm with an example of execution. In figure 6, we assume a simple configuration with 4 nodes (\( N_1, N_2, N_3 \), and \( N_4 \)) and 2 copies (\( R \) and \( S \)). \( N_1 \) carries a multi-owner copy of \( R \) and a primary copy of \( S \), \( N_2 \) a multi-owner copy of \( R \), \( N_3 \) a secondary copy of \( S \), and \( N_4 \) carries a multi-owner copy of \( R \) and a secondary copy of \( S \).

![Example of preventive refreshment with partial configurations.](image-url)
The refreshment proceeds in 5 steps. In step 1, \( N_1 \) (the origin node) receives \( T \) from a client which reads \( S \) and updates \( R_1 \). For instance, \( T \) can be the resulting read and write sequence produced by the transaction of figure 3. Then, in step 2, \( N_1 \) multicasts \( T \) to the involved target nodes, i.e. \( N_1, N_2 \) and \( N_4 \). \( N_3 \) is not concerned with \( T \) because it only holds a secondary copy \( s \). In step 3, \( T \) can be performed using the refreshment algorithm at \( N_1 \) and \( N_4 \). At \( N_2 \), \( T \) is also managed by the Refresher and then put in the running queue. However, \( T \) cannot yet be executed at this target node because \( N_2 \) does not hold \( S \). Thus, the Deliver needs to wait for its corresponding \( RT \) in order to apply the update on \( R \) (see step 4). In step 4, after the commitment of \( T \) at the origin node, the \( RT \) is produced and multicasts it to all involved target nodes. In step 5, \( N_2 \) receives \( RT \) and the Receiver replaces the content of \( T \) by the content of \( RT \). The Deliver can then submit \( RT \).

Partial replication may be blocking in case of failures. After the reception of \( T \), some target nodes would be waiting for \( RT \). Thus, if the origin node fails, the target nodes are blocked. However, this drawback can be easily solved by replacing the origin node by an equivalent node, a node that holds all the replicas necessary to execute \( T \). Once the target nodes detect the failure of the origin node, it can request an equivalent node \( j \) to multicast \( RT \) given \( T \)'s identifier. At node \( j \), \( RT \) was already produced in the same way that at the origin node: transaction \( T \) is executed and, upon detection of \( T \)'s commitment, an \( RT \) is produced and stored in a \( RT \) log (see Section 4.4), necessary to handle failure of the origin node. In the worst case where no other node holds all the replicas necessary to execute \( T \), \( T \) is globally aborted. Reconsider the example in figure 6: if \( N_1 \) fails at Step 3, \( N_2 \) can not receive the \( RT \) corresponding to the waiting \( T \). So, once \( N_2 \) detects that \( N_1 \) is out of service, it can identify that \( N_4 \) has all copies necessary for \( T \) (remember that the global data placement is known) and request the transfer of \( RT \) to \( N_4 \). So, we assume that \( RT \)'s logs are kept at each node (see Section 4.4). In addition, if \( N_4 \) is also out of service, then no node can perform \( T \). Thus, \( N_2 \) would abort transaction \( T \). Consistency is enforced because none of the active nodes has performed the transaction. In this case, at recovery time, the failed nodes would undo \( T \).

### 4.3. Correctness of the refresher algorithm

In this section we show that the refresher algorithm is correct. The proofs for the lazy master based configurations appear in [12] and we do not re-discuss them here. The proofs for partial configurations we consider come directly from those of lazy-master and multi-master configurations, as we will show.

**Lemma 4.1.** The refreshment algorithm is correct for multi-master configurations.

**Proof:** Let us consider any node \( N \) of a multi-master configuration holding multi-owner copies. Let \( T \) be any transaction committed by node \( N \). The propagator located at node \( N \) will propagate the operations performed by \( T \) by means of a message using reliable multicast. Hence any node involved in the execution of the transaction receives the update message. Since (i) the message containing the timestamp of any transaction \( T \) is the last one related to that transaction, and (ii) the reliable multicast preserves the global FIFO order,
when a node $N'$ receives the message containing the timestamp of $T$ (i.e., at delivery time $C + \text{Max} + \epsilon$), it has previously received all operations related to $T$ and involving that node. Hence the transaction can be committed when all its operations are done and earliest at delivery time $C + \text{Max} + \epsilon$. □

**Lemma 4.2.** The refreshment algorithm is correct for partial configurations.

**Proof:** Let us consider any node $N$ of a partial configuration holding at least one multi-owner copy. Let $T$ be any transaction submitted to node $N$, so $N$ is the origin node of $T$. When the update message is received by any node involved in the execution of the transaction, by Lemma 4.1, transaction $T$ can be committed when all its operations are done and earliest at delivery time $C + \text{Max} + \epsilon$. But in the case where the node does not hold all the copies necessary to the transaction, $T$ waits. Since an origin node must hold all the copies necessary to the transaction submitted by a client, the node $N$ can perform $T$. Then, node $N$ produces and multicasts $RT$ which contains the write set associated to $T$ to all waiting target nodes. So, the waiting target nodes can perform $T$ by replacing the content of the transaction by its write set. Hence the transaction is still committed earliest at delivery time $C + \text{Max} + \epsilon$. □

**Lemma 4.3 (Transaction chronological order).** The refreshment algorithm ensures that, if $T_1$ and $T_2$ are any two transactions that start execution at global times $t_1$ and $t_2$, respectively, then: if $t_2 - t_1 > \epsilon$, the timestamps $C_2$ for $T_2$ and $C_1$ for $T_1$ satisfy $C_2 > C_1$; any node that commits both $T_1'$ and $T_2'$, commits them in the order given by $C_1$ and $C_2$.

**Proof:** Let us assume that $t_2 - t_1 > \epsilon$. Even if the clock of the node committing $T_1$ is $\epsilon$ ahead with regard to the clock of the node committing $T_2$, we have $C_2 > C_1$. We now assume that we have $C_2 > C_1$ and we consider a node $N$ that commits first $T_1'$ and then $T_2'$. According to the algorithm, $T_2'$ is not committed before local time $C_2 + \text{Max} + \epsilon$. At that time, if $N$ commits $T_2'$ before $T_1'$, it means that $N$ has not received the message related to $T_1$. Since clocks are $\epsilon$ synchronised, that message would have experienced a multicast delay higher than $\text{Max}$. □

**Lemma 4.4 (Total order).** The refreshment algorithm satisfies the total order criterion for any configurations.

**Proof:** If the refreshment algorithm is correct (Lemmas 4.1 and 4.2) and the transactions are performed in chronological order on each node (Lemma 4.3), then the total order is enforced. □
4.4. Replication Manager architecture

In this section, we present the Replication Manager architecture to implement the Preventive Partial Replication algorithm (see figure 7). We add several components to a regular DBMS while preserving node autonomy, i.e. without requiring the knowledge of system internals. The Replica Interface receives transactions coming from the clients. The Propagator and the Receiver manage the sending and reception (respectively) of transactions and refresh transactions inside messages within the network.

Whenever the Receiver receives a transaction, it places it in the appropriate pending queue, used by the Refresher, and in the running queue used by the Deliver to start its execution. Next, the Refresher executes the refreshment algorithm to ensure strong consistency. The Deliver submits transactions, read from the running queue, to the DBMS and commits them only when the Refresher ensures that the transactions have been performed in chronological order.

With partial replication, when a transaction $T$ is composed of a sequence of reads and writes, the Refresher at the target nodes must assure correct ordering. However, in case where the node does not hold all the necessary copies, $T$’s execution must be delayed until its corresponding refresh transaction $RT$ is received. This is because $RT$ is produced only after the commitment of the corresponding $T$ at the origin node. At the target node, the content of $T$ (sequence of read and write operations) is replaced by the content of the $RT$ (sequence of write operations) in the Deliver. Thus, at the target node, when the Receiver receives $RT$, it interacts directly with Deliver.

The Log Monitor constantly checks the content of the DBMS log to detect whether replicas have been updated. For each transaction $T$ that updated a replica, it produces a corresponding refresh transaction. At the origin node, whenever the corresponding transaction is composed of reads and writes and some of the target nodes do not hold all the necessary replicas, the Log Monitor submits the refresh transaction to the propagator, which multicasts it to
those nodes. Then, upon receipt of the refresh transaction, the target nodes can perform the corresponding waiting transaction. To provide fault-tolerance in case of failure of the origin node (see Section 4.2), Log Monitor stores \( RT \), in addition to the origin node, in all the nodes that are able to perform the transaction (nodes which hold all necessary replicas to perform a transaction \( T \)). Thus, in case of failure of the origin node, one of these nodes can replace the origin node and multicast the \( RT \) to the target nodes that can not perform the corresponding \( T \).

5. Improving response time

In this section, we present optimizations for both Full and Partial Replication that improve transaction throughput. First, we modify the algorithm to eliminate partially the delay times \( (\text{Max} + \varepsilon) \) before submitting transactions. Then, we introduce concurrency control features in the algorithm to improve transaction throughput. Finally, we show the correctness of these optimizations.

5.1. Eliminating delay time

In a cluster network (which is typically fast and reliable), in most cases messages are naturally chronologically ordered [16]. Only a few messages can be received in an order that is different than the sending order. Based on this property, we can improve our algorithm by submitting a transaction to execution as soon as it is received, thus avoiding the delay before submitting transactions. Yet, we still need to guarantee strong consistency. In order to do so, we schedule the commit order of the transactions in such a way that a transaction can be committed only after \( \text{Max} + \varepsilon \). Recall that to enforce strong consistency, all the transactions must be performed according to their timestamp order. So, a transaction is out-of-order when its timestamp is lower than the timestamps of the transactions already received. Thus, when a transaction \( T \) is received out-of-order, all younger transactions must be aborted and re-submitted according to their correct timestamp order with respect to \( T \). Therefore, all transactions are committed in their timestamp order.

Thus, in most cases the delay time \( (\text{Max} + \varepsilon) \) is eliminated. Let \( t \) be the time to execute transaction \( T \). In the previous algorithm [13], the time spent to refresh a multi-master copy, after reception of \( T \), is \( \text{Max} + \varepsilon + t \). Now, a transaction \( T \) is ordered while it is executed. So, the time to refresh a multi-master copy is \( \text{max}[(\text{Max} + \varepsilon), t] \). In most cases, \( t \) is higher than the delay \( \text{Max} + \varepsilon \). Thus, this simple optimization can well improve throughput as we show in our performance study.

Figure 8 shows part of the components necessary to run our algorithm. The Refresher reads transactions from the head of pending queues and performs chronological ordering with respect to the delivery times. Once a transaction \( T \) is ordered, the refresher notifies Deliver that \( T \) is ordered and ready to be committed. Meanwhile, Deliver keeps checking the head of the running queue to start transaction execution optimistically, one after the other, inside the local DBMS. However, to enforce strong consistency Deliver only commits a transaction when the Refresher has signaled it.

Let us illustrate the algorithm with an example from figure 8. Suppose we have a node \( i \) that holds the master of the copy \( R \). Node \( i \) receives \( T_1 \) and \( T_2 \), two transactions that update
Refreshing architecture. $R_1$, respectively from node $i$ with a timestamp $C_1 = 10$ and from node $j$ with a timestamp $C_2 = 15$. $T_1$ and $T_2$ must be performed in chronological order, $T_1$ then $T_2$. Let us see what happens when the messages are not received chronologically ordered at node $i$. In our example, $T_2$ is received before $T_1$ at node $i$ and immediately written into the running queue and the corresponding pending queue. Thus, $T_2$ is submitted to execution by the Deliver but must wait the Refresher’s decision to commit $T_2$. Meanwhile, $T_1$ is received at node $i$, it is similarly written into both pending and running queues. However the Refresher detects that the younger transaction $T_2$ has already been submitted before $T_1$. So, $T_2$ is aborted and re-started, causing it to be re-inserted into the running queue (after $T_1$). $T_1$ is then chosen to be the next transaction to commit. Finally, $T_2$ is performed and elected to commit by Refresher. Thus, the transactions are committed in their timestamp order, even if they have been received unordered.

Preventive algorithm details. We can define three different states for a transaction $T$ represented in figure 9. When a transaction $T$ arrives at the Replication Manager, its state is

![Figure 8. Refreshment architecture.](image)

![Figure 9. Transition state graph for $T$.](image)
initialized to \textit{wait}. Then, when $T$ can be executed (a transaction can be executed when the node holds all necessary replicas or when its corresponding $RT$ is received), and when the Refresher has ordered the transaction, the state of Transaction $T$ is set to \textit{commit}. Finally, when the Deliver receives an out-of-order transaction $T$ (its timestamp is lower than the timestamps of the transactions already received), the state of the current running transactions is set to \textit{abort}.

The Preventive algorithm is described in detail in figures 10 and 11. Figure 10 describes the Refresher algorithm. The Refresher selects the next totally ordered transaction. A transaction is guaranteed to be totally ordered at its delivery time ($C + Max + \varepsilon$). Thus, in step 1, on the arrival of a new transaction, the refresher chooses the oldest transaction $T$

```
**Partial Replication Refresher**

Input:
- pending queues q1,...,qn

Variables:
- curr_T: currently selected transaction to be ordered;
- first_T: transaction with the lowest timestamp in the pending queues;
- running_T: transactions in the running queue;
- timer: local reverse timer whose state is either active or inactive;

Begin
- timer.state = inactive;
- curr_T = 0

Repeat

Step 1:
- On arrival of a new transaction in the pending queue
  - or when timer expires do
  - first_T <- message with min timestamp among top messages of the pending queues;
  - If first_T <> curr_T then
    - curr_T <- first_T;
    - calculate delivery_time(curr_T);
    - timer.value <- delivery_time(curr_T) - local_time
    - timer.state <- active;
  - end if

Step 2:
- If timer expires then
  - For all transactions running_T in the running queue
    - running_M.state = commit;
  - end for;
  - Dequeue curr_T from its pending queue;
  - timer.state <- inactive;
- end if;
- for ever;
end;
```

*Figure 10.* Partial replication refresher algorithm with elimination of delay times.
Partial Replication Deliver (no concurrency)

Input:
running queue, RT list

Variables:
new_T: new incoming transactions from the running queue
curr_T: currently running transaction;
new_RT: new incoming refresh transactions from the RT list

Begin
curr_T = 0;
Repeat
On arrival of a new transaction new_T
or at the end of curr_T
or the state of curr_T changes
or on arrival of new refresh transaction new_RT do

Step 1:
If curr_T finishes performing then
If curr_T.state = abort then
Rollback curr_T;
Dequeue curr_T from the running queue;
curr_T = 0;
elseif curr_T.state = commit then
Commit curr_T;
Dequeue curr_T from the running queue;
curr_T = 0;
endif;
endif;

Step 2:
If new_T <> 0 then
new_T.state = wait;
If curr_T <> 0 and curr_T.C > new_T.C then
curr_T.state = abort;
Introduce a copy of curr_T in the running queue
according to its timestamp with a wait state;
end if;
endif;

Step 3:
If curr_T = 0 and the running queue is not empty then
curr_T <- the transaction at the top of
the running queue;
If node holds all copies necessary to curr_T then
curr_T.standby = false;
Perform curr_T;
elcse,
curr_T.standby = true;
end if;
endif;

Step 4:
If curr_T <> 0 and curr_T.standby = true then
Extract the new_RT corresponding to curr_T from RT_list;
If new_RT <> 0 then
new_RT.state = curr_T.state;
curr_T = new_RT;
curr_T.standby = false;
Perform curr_T;
end if;
endif;
for ever;
end;

Figure 11. Partial replication deliver algorithm with elimination of delay times.
from the top of the pending queues and computes \( T \)’s delivery time. Next the Refresher initializes a timer that will expire at \( T \)’s delivery time. So, if the incoming transaction \( T \) is not out-of-order according to the current selected transaction, \( curr_T \), nothing happens. In the other case, the new \( T \)’s delivery time is calculated according to \( T \)’s timestamp. In step 2, when the timer expires, the Refresher looks for the non aborted transactions corresponding to \( curr_T \). Then, it sets the state of \( curr_T \) to commit.

Figure 11 describes the Deliver algorithm in the optimistic arrival approach. Deliver reads transactions from the running queue and executes them. If a transaction \( T \) is out-of-order, Deliver aborts the current running transaction, \( curr_T \), and executes \( T \) followed by \( curr_T \). Deliver commits a transaction when the Refresher sets its state to commit. In step 1, at the end of the execution of the current transaction \( curr_T \), Deliver commits or rolls-back \( curr_T \) according to its state (commit or abort). Since we do not have access to the transaction manager of the DBMS, we cannot abort directly the transactions and we must wait until the end of the transaction to abort it. In step 2, Deliver sets the state of the newly received transaction (\( new_T \)) to wait and checks whether \( new_T \) is not an out-of-order transaction. If the transaction is out-of-order, the state of the current transaction (\( curr_T \)) is set to abort. As the Deliver has to wait the end the transaction to rollback the transaction, a copy of \( curr_T \) is reintroduced in the running queue and its state is set to wait while the aborted \( curr_T \) is running. Thus, a transaction \( T \) aborted due to an unordered message will be re executed from a copy of \( curr_T \). In step 3, the Refresher selects the transaction at the top of the running queue and performs it if the node holds all the copies necessary to the transaction. Otherwise, the Refresher set the transaction in stand by. Finally, in step 4, on arrival of a new refresh transaction \( new_RT \), the Deliver replaces the content of the waiting \( T \) by the content of its corresponding \( RT \). So, the current transaction can execute.

5.2. Improving transaction throughput

To improve throughput, we now introduce concurrent replica refreshment. In the previous section, the Receiver writes transactions directly into the running queue (optimistically), and afterwards the Deliver reads the running queue contents in order to execute the transaction, and in the other hand, to assure consistency, the same transactions are written as usually in the pending queues to be ordered by the Refresher. Hence, the Deliver extracts the transactions from the running queue and performs them one by one in serial order. So, if the Receiver fills the running queue faster than the Deliver empties it, and if the average arrival rate is higher than the average running rate of a transaction (typically in bursty workloads), the response time increases exponentially and performance degrades.

To improve response time in bursty workloads we propose to trigger transactions concurrently. In our solution, concurrency management is done outside the database to preserve autonomy (different from [9]). Using the existing isolation property of database systems [11], at each node, we can guarantee that each transaction sees a consistent database at all times. To maintain strong consistency at all nodes, we enforce that transactions are committed in the same order in which they are submitted. In addition, we guarantee that transactions are submitted in the order in which they have been written to the running queue. Thus, total order is always enforced.
However, without access to the DBMS concurrency controller (for autonomy reasons), we cannot guarantee that two conflicting concurrent transactions obtain a lock in the same order at two different nodes. Therefore, we do not trigger conflicting transactions concurrently. To detect that two transactions are conflicting, we determine a subset of the database items accessed by the transaction according to the transaction. If the subset of a transaction does not intersect with a subset of another transaction, then the transactions are not conflicting. For example, in the TPC-C benchmark, the transactions’ parameters allow us to define a subset of tuples that could be read or updated by the transaction. Notice that if the subset of the transaction cannot be determined, then we consider the transaction to be conflicting with all other transactions. This solution is efficient if most transactions are known, which is true in OLTP environments.

We can now define two new conditions to be verified by the Deliver before triggering and before committing a transaction:

(i) Start a transaction iff the transaction is not conflicting with transactions already started (but not committed) and iff no older transaction waits for the commitment of a conflicting transaction to start.

(ii) Commit a transaction iff no older transactions are still running.

Figure 12 shows examples of concurrent executions of transactions. Figure 12(a) illustrates a case where the transactions are triggered sequentially, which is equivalent to the case where all the transactions are conflicting. Figures 12(b), (c) and (d) show parallel executions of transaction $T_1$, $T_2$ and $T_3$. In figures 12(b) and (c), transaction $T_2$ finishes before $T_1$ but waits for commit because $T_1$ is still running (this is represented by a dashed line in the figure). In figure 12(b), $T_1$, $T_2$ and $T_3$ are not conflicting, so they can run concurrently. On the other hand, in figure 12(c), $T_2$ is conflicting with $T_3$, so $T_3$ must wait for the end of $T_2$ before starting. Finally, in figure 12(d), $T_1$ and $T_2$ are conflicting, so $T_2$ cannot start before the commitment of $T_1$ and $T_3$ cannot start before $T_2$ because transactions must be executed in the order they are in the running queue.
5.3. Correctness

In this section, we prove that the Preventive Replication algorithm is also correct with the optimizations.

Lemma 5.1. The elimination of the delay $\text{Max} + \varepsilon$ does not introduce inconsistency.

**Proof:** Let $T_1$ and $T_2$ be any two transactions with timestamps $C_1$ and $C_2$. If $T_1$ is older than $T_2$ ($C_1 < C_2$) and $T_2$ is received on node $i$ before $T_1$, then $T_2$ is managed optimistically. However, $T_2$ cannot be committed before $C_2 + \text{Max} + \varepsilon$, and as $T_1$ is received at node $i$ at the latest at $C_1 + \text{Max} + \varepsilon$, then, $T_1$ is received before $T_2$ is committed ($C_1 + \text{Max} + \varepsilon < C_2 + \text{Max} + \varepsilon$). Therefore, $T_2$ is aborted, and both transactions are written in the running queue, executed and committed according to their timestamp values. Afterwards, $T_1$ is executed before $T_2$, and the strong consistency is enforced even in the case of unordered messages.

Lemma 5.2. The parallel execution of transactions does not break the enforcement of strong consistency.

**Proof:** Let $T_1$ and $T_2$ be any two transactions with timestamps $C_1$ and $C_2$ that start execution at times $t_1$ and $t_2$, and commit at times $c_1$ and $c_2$, respectively. In the case where $T_1$ and $T_2$ are received unordered, the transactions are aborted and re-executed in the correct order as described in Lemma 5.2. Now, in the case where the transactions are received correctly ordered, if $T_1$ and $T_2$ are conflicting, they start and commit one after the other according to their timestamp values. Hence, if $C_1 < C_2$, then $t_1 < c_1 < t_2 < c_2$. If they are not conflicting, $T_2$ can start before $T_1$ commits. However, a transaction is never committed before all older transactions have been committed. If $C_1 < C_2$, then $t_1 < t_2$ and $c_1 < c_2$. Thus, the state of the database viewed by a transaction before its execution and its commitment is the same at all the nodes. Hence, strong consistency is enforced.

6. Validation

In this section, we describe our implementation and our performance model. Then, we describe two experiments to study scale up and speed-up.

6.1. Implementation

We implemented our Preventive Replication Manager in our RepDB* prototype [2, 19] on a cluster of 64 nodes (128 processors). Each node has 2 Intel Xeon 2.4 GHz processors, 1 GB of memory and 40 GB of disk. The nodes are linked by a 1 Gb/s network. We use Linux Mandrake 8.0/Java and CNDS’s Spread toolkit that provides a reliable FIFO message bus and high-performance message service among the cluster nodes. We use PostgreSQL Open Source DBMS at each node. We chose PostgreSQL because it is quite complete in terms of transaction support and easy to work with.
Our implementation has four modules: Client, Replicator, Network and Database Server. The Client module simulates the clients. It submits transactions randomly to any cluster node, via RMI-JDBC, which implements the Replica Interface. Each cluster node hosts a Database Server and one instance of the Replicator module. For this validation, we implemented most of the Replicator module in Java outside of PostgreSQL. For efficiency, we implemented the Log Monitor module inside PostgreSQL. The Replicator module implements all system components necessary for a multi-master node: Replica Interface, Propagator, Receiver, Refresher and Deliver. Each time a transaction is to be executed, it is first sent to the Replica Interface that checks whether the incoming transaction updates a replica. Whenever a transaction does not write a replica, it is sent directly to the local transaction manager. Even though we do not consider node failures in our performance evaluation, we implemented all the necessary logs for recovery to understand the complete behavior of the algorithm. The Network module interconnects all cluster nodes through the Spread toolkit.

6.2. Performance model

To perform our experiments, we use the TPC-C Benchmark [18] which is an OLTP workload with a mix of read-only and update intensive transactions. It has 9 tables: Warehouse, District, Customer, Item, Stock, New-order, Order, Order-line and History; and 5 transactions: Order-status, Stock-level, New-order, Payment and Delivery.  

The parameters of the performance model are shown in Table 1. The values of these parameters are representative of typical OLTP applications. The size of the database is proportional to the number of warehouses (a tuple in the Warehouse table represents a warehouse). The number of warehouses also determines the number of clients that submit a transaction. As specified in the TPC-C benchmark, we use 10 clients per warehouse. For a client, we fix the transaction arrival rate $\lambda_{\text{client}}$ at 10 s. So with 100 clients (10 warehouses and 10 clients per warehouse), the average transactions’ arrival rate $\lambda$ is 100 ms. In our experiments, we vary the number of warehouses $W$ to be either 1, 5 or 10. Then, the different average transactions’ arrival rates are 1 s, 200 ms and 100 ms.

During an experiment, each client submits to a random node a transaction among the 4 TPC-C transactions used. In the end, each client must have submitted $M$ transactions.

Table 1. Performance parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Definition</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>$W$</td>
<td>Number of warehouse</td>
<td>1, 5, 10</td>
</tr>
<tr>
<td>Clients</td>
<td>Number of clients by warehouse</td>
<td>10</td>
</tr>
<tr>
<td>$\lambda_{\text{client}}$</td>
<td>Average arrival rate for each client</td>
<td>10 s</td>
</tr>
<tr>
<td>$\lambda$</td>
<td>Average arrival rate</td>
<td>1 s, 200 ms, 100 ms</td>
</tr>
<tr>
<td>Conf.</td>
<td>Replication of tables</td>
<td>FR, PR</td>
</tr>
<tr>
<td>$M$</td>
<td>Number of transactions submitted during the tests for each client</td>
<td>100</td>
</tr>
<tr>
<td>$\text{Max } + \epsilon$</td>
<td>Delay introduced for submitting a Transaction</td>
<td>200 ms</td>
</tr>
</tbody>
</table>
and must have maintained a percentage of mixed transactions: 6% for Order-status, 6% for Stock-level, 45% for New-order and 43% for Payment.

The TPC-C defines a number of different types of transactions. New-order represents a mid-weight, read-write transaction with a high frequency of execution. Payment represents a lightweight, read-write transaction with a high frequency of execution. Order-status represents a mid-weight, read-only transaction with a low frequency of execution. Stock-level represents a heavy, read-only transaction with a low frequency of execution. Thus, we can consider New-order and Payment as multi-master transactions.

Finally, for our experiments, we use two replication configurations. In the Fully Replicated (FR) configuration all the nodes carry all the tables as multi-master copies. In the Partially Replicated (PR) configuration, one fourth of the nodes hold tables needed by the Order-status transaction as multi-master copies, another fourth holds tables needed by the New-order transaction as multi-master copies, another fourth holds tables needed by the Payment transaction as multi-master copies and the last fourth holds tables needed by the Stock-level transaction as multi-master copies.

6.3. Scale up experiments

These experiments study the algorithm’s scalability. That is, for a same set of incoming transactions (New-order and Payment transactions), scalability is achieved whenever increasing the number of nodes yields the same response times. We vary the number of nodes for each configuration (FR and PR) and for different numbers of warehouses (1, 5 and 10). For each test, we measure the average response time per transaction. The duration of this experiment is the time to submit 100 transactions for each client.

The experimental results (see figure 13) show that for all tests, scalability is achieved. The performance remains relatively constant according to the number of nodes. Our algorithm has linear response time behavior even when the number of node increases. Let $n$ be the number of target nodes for each incoming transaction, our algorithm requires only the multicast of $n$ messages for the nodes that carry all required copies.

Figure 13. Scale up results.
plus $2n$ messages for the nodes that do not carry all required copies. The performance decreases as the number of warehouses increases (which increases the workload). In figure 13(a), although the workload is twice higher for 10 warehouses than for 5 warehouses, the response times remain twice as worse as expected, i.e., 400 ms for 5 warehouses and about 800 ms for 10 warehouses. This demonstrates that our algorithm has good response time when the workload increases and we can expect similar behavior with higher workloads.

The results also show the impact of the configuration on transaction response time. As the number of transactions increases (with the number of nodes that receive incoming transactions), $PR$ increases inter-transaction parallelism more than $FR$ by allowing different nodes to process different transactions. Thus, transaction response time is slightly better with $PR$ (figure 13(a)) than with $FR$ (figure 13(b)) by about 15%. In $PR$, nodes only hold tables needed by one type of transaction, so they do not have to perform the entire updates of the other type of transactions. Hence, they are less overloaded than in $FR$. Thus the configuration and the placement of the copies should be tuned to selected types of transactions.

6.4. Speed-up experiments

These experiments study the performance improvement (speed-up) for read queries when we increase the number of nodes. To test speed-up, we reproduced the previous experiments and we introduced clients that submit queries. We vary the number of nodes for each configuration ($FR$ and $PR$) and for different number of warehouses (1, 5 and 10). The duration of this experiment is the time to submit 100 transactions for each client.

The number of clients that submit queries is 128. The clients submit lightweight queries (Order-status transaction) sequentially while the experiment is running. Each client is associated to one node and we produce an even distribution of clients at each node. Thus, the number of read clients per node is 128 divided by the number of nodes that support the

![Figure 14. Speed-up results.](image-url)
Order-status transaction. For each test, we measured the throughput of the cluster, i.e. the number of read queries per second.

The experiment results (see figure 14) show that the increase in the number of nodes improves the cluster’s throughput. For example in figure 14(a), whatever the number of warehouses, the number of queries per seconds with 32 nodes (1500 queries per seconds) is almost twice that with 16 nodes (800 queries per seconds). However, if we compare FR with PR, we can see that the throughput is better with FR. Although the nodes are less overloaded than in FR, performance is half of FR because only half of the nodes support the transaction. This is due to the fact that, in PR, not all the nodes hold all the tables needed by the read transactions. In FR, beyond 48 nodes, the throughput does not increase anymore because the optimal number of nodes is reached, and the queries are performed as fast as possible.

6.5. Effect of optimistic execution

Now, we study the effect of optimistically executing transactions as soon as they arrive. Our first study shows the impact of the unordered messages on the number of aborted transactions due to optimistic execution (see Section 5.1). Then, our second study shows the gain of the optimistic approach on the refreshment delay.

In our first experiment, figures 15(a) and (b) show the percentage of the unordered messages and the percentage of the aborted transactions for the scale up experiment (Section 6.3). Below 5% of the messages are unordered, and only 1% of the transactions are aborted. At most only 20% of the unordered messages introduce aborts because two unordered messages are received in a very short period of time (around 2 ms). So, the second message is received before the first message has been processed. Therefore, they are reordered before the execution of the first message.

For PR, the Partially Replicated configuration (figure 15(b)), the percentage of the unordered messages is lower than the percentage for FR, the Fully Replicated configuration
In our second experiment, we study how the transaction size affects the elimination of the refreshment delay. In the Optimistic Approach, transactions still need to be delayed \((\text{Max} + \varepsilon)\) before committing. Figure 16 shows the relative importance of the delay time with respect to transaction size. Our test involves only 8 nodes with a FR configuration because the waiting time is not affected by the increase of the number of nodes. We submit 100 transactions in a low workload and we vary the size of the transaction. Then, we measure the delay time introduced by the refreshment algorithm. Recall that the normal delay (Max) value is 200 ms without optimization.

An important observation is that the delay introduced by the refreshment quickly decreases as the transaction time increases. This is due to the fact that, since the transaction is performed as soon as possible, the scheduling of a transaction is performed in parallel with its execution. As the scheduling time is equal to \(\text{Max} + \varepsilon\), the delay introduced is equal to \(\text{Max} + \varepsilon\) minus the size of the transaction. For example, with a transaction size of 50 ms, the delay is 150 ms. Thus, with transactions longer than 200 ms, the delay is almost zero because the scheduling time is included in the execution time. Hence, the gain is almost equal to Max, which is the optimal gain for the elimination of Max. Finally, the number of aborted transactions is not enough significant, so we do not put it on the figure.

7. Related work

Data replication has been extensively studied in the context of distributed database systems [11]. In the context of database clusters, the main issue is to provide scalability (to achieve performance with large numbers of nodes) and autonomy (to exploit black-box DBMS) for various replication configurations such as master-slave, multi-master and partial replication.

Synchronous (eager) replication can provide strong consistency for most configurations including multi-master but its implementation, typically through 2PC, violates system
autonomy and does not scale up. In addition, 2PC may block due to network or node failures. The synchronous solution proposed in [9] reduces the number of messages exchanged to commit transactions compared to 2PC. It uses, as we do, group communication services to guarantee that messages are delivered at each node according to some ordering criteria. However, DBMS autonomy is violated because the implementation must combine concurrency control with group communication primitives. In addition solutions based on total order broadcast is not well suited for large scale replication because as the number of nodes increases the overhead of messages exchanged may dramatically increase to assure total order. The Database State Machine [20, 21] supports partial replication for heterogeneous databases and thus does not violate autonomy. However, its synchronous protocol uses two-phase locking that is known for its poor scalability, thus making it inappropriate for database clusters.

Asynchronous (lazy) replication typically trades consistency for performance. A refreshment algorithm that assures correctness for lazy master configurations is proposed in [12]. This work does not consider multi-master and partial replication as we do. The preventive replication solution in [13] is asynchronous and achieves strong consistency for multi-master configurations. However, it introduces heavy message traffic in the network since transactions are multicast to all cluster nodes. In [3], we extended preventive replication to deal with partial replication. However, it also has performance limitations since transactions are forced to wait a delay time before executing. The solution proposed in this paper addresses these important limitations.

The algorithm proposed in [8] provides strong consistency for multi-master and partial replication while preserving DBMS autonomy. However, it requires that transactions update a fixed primary copy: each type of transaction is associated with one node so a transaction of that type can only be performed at that node. This is a problem for update intensive applications. For example, with the TPC-C benchmark, two nodes support 88% of the transactions (45% at one node for the New Order transactions and 43% at another node for the Payment transactions). Furthermore, the algorithm uses 2 messages to multicast the transaction, the first is a reliable multicast and the second is a total ordered multicast. The cost of these messages is higher than the single FIFO multicast message we use. Furthermore, using a logical total order message increases the overhead of physical messages exchanged when increasing the number of nodes. However, one advantage of this algorithm is that it avoids redundant work: the transaction is performed at the origin node and the target nodes only apply the write set of the transaction. In our algorithm, all the nodes that hold the resources necessary for the transaction perform it entirely. We could also remove this redundant work to generalize the multicast of refresh transactions for all nodes instead of only for the nodes that do not hold all the necessary replicas. However, the problem is to decide whether it is faster to perform the transaction entirely or to wait for the corresponding write set from the origin node for short transactions. Finally their experiments do not show scale-up with more than 15 nodes while we go up to 64 in our experiments.

More recent work has focused on snapshot isolation to improve the performance of read-only transactions. The RSI-PC [17] algorithm is a primary copy solution which separates update transactions from read-only transactions Update transactions are always routed to a main replica, whereas read-only transactions are handled by any of the remaining replicas,
which act as read-only copies. Postgres-R(SI) [24] proposes a smart solution that does not need to declare transactions properties in advance. It uses the replication algorithm of [8] which must be implemented inside the DBMS. The experiments are limited to at most 10 nodes. SI-Rep [10] provides a solution similar to Postgres-R(SI) on top of PostgreSQL which needs the write set of a transaction before its commitment. Write sets can be obtained by either extending the DBMS, thus hurting DBMS autonomy, or using triggers.

8. Conclusion

In this paper, we introduced two algorithms for preventive replication in order to scale up to large cluster configurations. The first algorithm supports fully replicated configurations where all the data are replicated on all the nodes, while the second algorithm supports partially replicated configurations, where only a part of the data are replicated. Both algorithms enforce strong consistency. Then, we proposed a complete architecture that supports a large numbers of configurations. Moreover, we presented two optimizations that improve transaction throughput; the first optimization eliminates optimistically the delay introduced by the preventive replication algorithm while the second optimization introduces concurrency control features outside the DBMS in which non conflicting incoming transactions may execute concurrently.

We did an extensive performance validation based on the implementation of Preventive Replication in our RepDB∗ prototype over a cluster of 64 nodes running PostgreSQL. Our experimental results using the TPC-C benchmark show that our algorithm scales up very well and has linear response time behavior. We also showed the impact of the configuration on transaction response time. With partial replication, there is more inter-transaction parallelism than with full replication because of the nodes being specialized to different tables and thus transaction types. Thus, transaction response time is better with partial replication than with full replication (by about 15%). The speed-up experiment results showed that the increase of the number of nodes can well improve the query throughput. Finally, we showed that, with our optimistic approach, unordered transactions introduce very few aborts (at most 1%) and that the waiting delay for committing transactions is very small (and reaches zero as transaction time increases). To summarize, the performance gains strongly depend on the types of transactions and of the configuration. Thus an important conclusion is that the configuration and the placement of the copies should be tuned to selected types of transactions.

Notes

1. For any two nodes, the same sequence of transactions is executed in the same order.
2. For our experiments, we do not use the delivery transaction because it is executed in a deferred mode that is not relevant to test the response times on which our measures are based.

Abstract. Collaborative applications are characterized by high levels of data sharing. Optimistic replication has been suggested as a mechanism to enable highly concurrent access to the shared data, whilst providing full application-defined consistency guarantees. Nowadays, there are a growing number of emerging cooperative applications adequate for Peer-to-Peer (P2P) networks. However, to enable the deployment of such applications in P2P networks, it is required a mechanism to deal with their high data sharing in dynamic, scalable and available way. Previous work on optimistic replication has mainly concentrated on centralized systems. Centralized approaches are inappropriate for a P2P setting due to their limited availability and vulnerability to failures and partitions from the network. In this paper, we focus on the design of a reconciliation algorithm designed to be deployed in large scale cooperative applications, such as P2P Wiki. The main contribution of this paper is a distributed reconciliation algorithm designed for P2P networks (P2P-reconciler). Other important contributions are: a basic cost model for computing communication costs in a DHT overlay network; a strategy for computing the cost of each reconciliation step taking into account the cost model; and an algorithm that dynamically selects the best nodes for each reconciliation step. Furthermore, since P2P networks are built independently of the underlying topology, which may cause high latencies and large overheads degrading performance, we also propose a topology-aware variant of our P2P-reconciler algorithm and show the important gains on using it. Our P2P-reconciler solution enables high levels of concurrency thanks to semantic reconciliation and yields high availability, excellent scalability, with acceptable performance and limited overhead.

1 Introduction

Large-scale distributed collaborative applications are getting common as a result of rapid progress in distributed technologies (grid, P2P, and mobile computing). As an example of such applications, consider a second generation Wiki that works over a peer-to-peer (P2P) network and supports users on the elaboration and maintenance of shared documents in a collaborative and asynchronous manner. Current wiki platforms rely on central servers that are costly and require an organization behind them to buy and maintain the hardware and to maintain the software. A P2P wiki would allow a community of users to collaborate by means of a wiki without having to create an organization to maintain the hardware resources. The computational resources would be provided by the community as a whole. This P2P environment would also allow for people updating the wiki whilst disconnected (e.g. whilst traveling) due to its reconciliation capabilities. In the P2P wiki example, consider that each document is an XML file possibly linked to other documents. Wiki allows collaboratively managing a single document (e.g. a scien-
tific paper shared by a few of authors) as well as composed, integrated documents (e.g. an encyclopedia or a knowledge base concerning the use of an open source operating system). Although the number of users that update in parallel a document $d$ is usually small, the size of the collaborative network that holds $d$ in terms of number of nodes may be large. For instance, the document $d$ could belong to the knowledge base of the Mandriva Club, which is maintained by more than 25,000 members [Man07] or it could belong to Wikipedia, a free content encyclopedia maintained by more than 75,000 active contributors [Wik07].

Many users frequently need to access and update information even if they are disconnected from the network, e.g. in an aircraft, a train or another environment that does not provide good network connection. This requires that users hold local replicas of shared documents. Thus, a P2P Wiki requires multi-master replication (any replica can perform updates, also known as update-everywhere replication) to assure data availability at anytime. In the multi-master approach, updates made offline or in parallel on different replicas of the same data may cause replica divergence and conflicts, which should be reconciled. In order to resolve conflicts, the reconciliation solution can take advantage of application semantics as illustrated in Example 1. For simplicity, and without loss of generality, this example deals with a single document elaborated by three authors. The document is a scientific paper organized as a tree. Each node (element) in the tree structure corresponds to a section of the paper and holds the name of the responsible author.

Example 1a shows the initial structure of the paper whereas Example 1b shows conflicting updates (in gray) over the initial structure. In Example 1b Phil tries to move the Background section under Paper thereby changing the Background path from Paper/Solution/Background to Paper/Background while Mary tries to insert two topics under Background using the path Paper/Solution/Background. If the move operation is accomplished before the insert operations, the Background’s path changes so that the insert operations do not find the Background element, and therefore such inserts are lost. We can automatically solve this problem by introducing the following application semantics: update operations precede move operations. In Example 1, according to this semantics, Topic 1 and Topic 2 are inserted in the path Paper/Solution/Background, and then the entire subtree under Background is moved in such a way that the intents of both users (Phil and Mary) are preserved.

![Example 1](image.png)

**Example 1.** Producing a paper in a collaborative manner

The semantics associated with a P2P collaborative editor can be richer than the simple semantics that we have just discussed. However, we made the example deliberately simple only to show that, by taking advantage of the application semantics on the reconciliation, we can eliminate spurious update conflicts.
(e.g. insert and move operations over the same element are not really conflicting operations) and we can resolve the real existing conflicts in an automatic manner as users wish.

Optimistic replication is largely used as a solution to provide data availability for these applications. It allows asynchronous updating of replicas such that applications can progress even though some nodes are disconnected or have failed. This enables asynchronous collaboration among users. However, concurrent updates may cause replica divergence and conflicts, which should be reconciled. In most existing solutions [PSM03, SS05] reconciliation is typically performed by a single node (reconciler node) which may introduce bottlenecks. In addition, if the reconciler node fails, the entire replication system may become unavailable.

A theory for centralized semantic reconciliation was set by IceCube [KRSD01, PSM03]. According to this theory, the application semantics can be described by means of constraints between update actions. A constraint is an application invariant, e.g. a parcel constraint establishes the “all-or-nothing” semantics, i.e. either all parcel’s actions execute successfully in any order, or none does. For instance, consider a user that improves the content of a shared document by producing two related actions $a_1$ and $a_2$ (e.g. $a_1$ changes a document paragraph and $a_2$ changes the corresponding translation); in order to assure the “all-or-nothing” semantics, the application should create a parcel constraint between $a_1$ and $a_2$. These actions can conflict with other actions. Therefore, the aim of reconciliation is to take a set of actions with the associated constraints and produce a schedule, i.e. a list of ordered actions that do not violate constraints.

Different from IceCube, we propose a fully distributed approach to perform P2P reconciliation in a distributed hash table (DHT) overlay. The DHT is an efficient distributed architecture to perform key-based information retrieval in a P2P environment. Since our reconciliation solution relies on key-based information retrieval and aims at providing good performance, the choice of DHT seems natural. In addition, variable latencies and bandwidths, typically found in P2P networks, may strongly impact the reconciliation performance once data access times may vary significantly from node to node. Therefore, in order to build a suitable P2P reconciliation solution, topology awareness must be considered. In this paper we also introduce topology awareness to our distributed algorithms, to enhance the reconciliation performance.

In this paper, we propose the P2P-reconciler, a new decentralized reconciliation protocol designed for P2P networks that we built upon the reconciliation theory set by IceCube. The main contributions of this paper are: (1) a DHT cost model for computing communication costs of a P2P network using a DHT overlay network; (2) the P2P-reconciler cost model for computing the cost of each reconciliation step based on DHT cost model; (3) the basic P2P-reconciler algorithm for semantic reconciliation in P2P networks, which selects the best reconciler nodes based on the P2P-reconciler cost model; (4) a topology-aware approach for the P2P-reconciler (P2P-reconciler-TA); (5) experimental results that show: a) that our cost-based approach yields high data availability and excellent scalability, with acceptable performance and limited overhead; b) the important gains of the topology-aware approach (P2P-reconciler-TA) compared to the basic P2P-reconciler. We also present the validation of P2P-reconciler through its implementation in the APPA architecture [MAPV06] and give the proof of correctness of our protocols.

The rest of this paper is organized as follows. Section 2 describes the basis of the P2P-reconciler protocol for semantic reconciliation in P2P networks. Section 3 introduces the DHT cost model. Section 4 describes the P2P-reconciler cost model and the dynamic allocation algorithm for selecting the best reconciler nodes. Section 5 presents the topology aware approach for the P2P-reconciler. Section 5 shows implementation and experimental results. Section 6 compares our work with the most relevant related works. Finally, Section 7 concludes this paper. Annex A shows the validation of P2P-reconciler built in the context of APPA and Annex B presents all proofs of correctness of our protocols.
2 P2P semantic reconciliation

In this section, we first introduce the semantic reconciliation as proposed by IceCube. Then, we provide an overview of our P2P-reconciler. Next, we present P2P-reconciler in detail. Finally, we describe our strategy for dealing with the dynamic behavior of the P2P network.

2.1 Representation of application semantics

IceCube describes the application semantics by means of constraints between actions. An action is defined by the application programmer and represents an application-specific operation (e.g. a write operation on a file or document, or a database transaction). A constraint is the formal representation of an application invariant (e.g. an update cannot follow a delete). Constraints are classified as follows:

- **User-defined constraints**: user and application can create user-defined constraints to make their intents explicit. The predSucc($a_1$, $a_2$) constraint establishes causal ordering between actions (i.e. action $a_2$ executes only after $a_1$ has succeeded); the parcel($a_1$, $a_2$) constraint is an atomic (all-or-nothing) grouping (i.e. either $a_1$ and $a_2$ execute successfully or none does); the alternative($a_1$, $a_2$) constraint provides choice of at most one action (i.e. either $a_1$ or $a_2$ is executed, but not both).

- **System-defined constraints**: it describes a semantic relation between classes of concurrent actions. The bestOrder($a_1$, $a_2$) constraint indicates the preference to schedule $a_1$ before $a_2$ (e.g. an application for account management usually prefers to schedule credits before debits); the mutuallyExclusive($a_1$, $a_2$) constraint states that either $a_1$ or $a_2$ can be executed, but not both.

Let us illustrate user- and system-defined constraints with Example 2. In this example, an action is noted $a_i^n$, where $n$ indicates the node that has executed the action and $i$ is the action identifier. $T$ is a replicated object, in this case, a relational table; $K$ is the key attribute for $T$; $A$ and $B$ are any two other attributes of $T$. $T_1$, $T_2$, and $T_3$ are replicas of $T$. And parcel is a user-defined constraint that imposes atomic execution for $a_i^1$ and $a_i^2$. Consider that the actions in Example 2 (with the associated constraints) are concurrently produced by nodes $n_1$, $n_2$ and $n_3$, and should be reconciled.

\[
\begin{align*}
a_1^1: & \text{ update } T_1 \text{ set } A=a1 \text{ where } K=k1 \\
& a_2^1: \text{ update } T_2 \text{ set } A=a2 \text{ where } K=k1 \\
& a_1^2: \text{ update } T_1 \text{ set } B=b1 \text{ where } K=k2 \\
& a_2^2: \text{ update } T_3 \text{ set } A=a3 \text{ where } K=k2 \\
& \text{ Parcel}(a_1^1, a_2^1)
\end{align*}
\]

**Example 2.** Conflicting actions on $T$

In Example 2, actions $a_1^1$ and $a_2^1$ try to update a copy of the same data item (i.e. $T$’s tuple identified by $k1$). The IceCube reconciliation engine realizes this conflict and asks the application for the semantic relationship involving $a_1^1$ and $a_2^1$. As a result, the application analyzes the intents of both actions, and, as they are really in conflict (i.e. $n_1$ and $n_2$ try to set the same attribute with distinct values), the application produces a mutuallyExclusive($a_1^1$, $a_2^1$) system-defined constraint to properly represent this semantic dependency. Notice that from the point of view of the reconciliation engine $a_1^1$ also conflicts with $a_1^1$ and $a_2^1$ (i.e. all these actions try to update a copy of the same data item). However, by analyzing actions’ intents, the application realizes that $a_1^1$ is semantically independent of $a_1^1$ and $a_2^1$ as $a_1^1$ tries to update another attribute (i.e. $B$). Therefore, in this case no system-defined constraints are produced. Actions $a_1^1$ and $a_1^2$ are involved in a parcel user-defined constraint, so they are semantically related.

---

2 User-defined constraints are called log constraints by IceCube. We prefer user-defined to emphasize the user intent.
3 System-defined constraints are called object constraints by IceCube. We use system-defined in contrast to user intents.
The aim of reconciliation is to take a set of actions with the associated constraints and produce a **schedule**, i.e. a list of ordered actions that do not violate constraints. In order to reduce the schedule production complexity, the set of actions to be ordered is divided into subsets called **clusters**. A cluster is a subset of actions related by constraints that can be ordered independently of other clusters. Therefore, the **global schedule** is composed by the concatenation of clusters’ ordered actions. To order a cluster, IceCube performs iteratively the following operations:

- Select the action with the highest merit from the cluster and put it into the schedule. The merit of an action is a value that represents the estimated benefit of putting it into the schedule (the larger the number of actions that can take part in a schedule containing \( a_i \) is, the larger the merit of \( a_i \) will be). If more than one action has the highest merit (different actions may have equal merits), the reconciliation engine selects randomly one of them.
- Remove the selected action from the cluster.
- Remove from the cluster the remaining actions that conflict with the selected action.

This iteration ends when the cluster becomes empty. As a result, cluster’s actions are ordered. In fact, several alternative orderings may be produced until finding the best one. Therefore, our approach does not employ timestamps. Indeed, actions are ordered based on the application semantics in such a way that the number of actions in the final schedule is maximized.

Let us illustrate our ordering procedure with an example. Consider the actions \( a_1, a_2, a_3 \) and the associated constraints \( \text{predSucc}(a_1, a_2) \) and \( \text{mutuallyExclusive}(a_1, a_2) \). The constraint \( \text{predSucc}(a_1, a_2) \) states that \( a_1 \) must precede \( a_2 \) in the schedule according to the application semantics. Similarly, the constraint \( \text{mutuallyExclusive}(a_1, a_2) \) states that either \( a_1 \) or \( a_2 \) should be scheduled, but not both. In this scenario, \( a_2 \) cannot be the first action in the schedule since it should be preceded by \( a_1 \). Thus, in the first iteration, we must choose between \( a_1 \) and \( a_2 \). The merit of \( a_1 \) is 1 since \( a_1 \) can be followed by \( a_2 \), whereas the merit of \( a_2 \) is 0. Therefore, the first action we put into the schedule based on actions’ merits is \( a_1 \). Due to the \( \text{mutuallyExclusive}(a_1, a_3) \) constraint, the selection of \( a_1 \) leads to the removal of \( a_3 \) and, as a result, \( a_2 \) remains alone to the next iteration. Thus, in the second iteration, we put \( a_2 \) into the schedule. In this example, the final schedule is ordered as follows: \([a_1, a_2]\).

### 2.2 Overview on how P2P-reconciler works

We assume that P2P-reconciler is used in the context of a virtual community which requires a high level of collaboration and it is deployed on a reasonable number of nodes (typically hundreds or even thousands of interacting users) [WIIO97]. The P2P network we consider consists of a set of nodes which are organized as a distributed hash table (DHT) [RFHK+01, SMKK+01]. A DHT provides a hash table abstraction over multiple computer nodes. Data placement in the DHT is determined by a hash function which maps data identifiers into nodes.

In our solution, the replicated object is generic, i.e. it can be a relational table, an XML document, etc. We call **object item** a component of the object, e.g. a tuple in a relational table or an element in an XML document. A **replica** is a copy of an object (e.g. copy of a relational table or an XML document) while a **replica item** is a copy of an object item (e.g. a copy of a tuple or XML element). We assume **multi-master** replication, i.e. multiple replicas of an object \( R \), noted \( R_1, R_2, \ldots, R_n \), are stored in different nodes which can read or write \( R_1, R_2, \ldots, R_n \). Conflicting updates are expected, but it is assumed that the application tolerates some level of replica divergence until reconciliation.

We have structured the P2P reconciliation in 6 distributed steps in order to maximize parallelism and assure independence between parallel activities. This structure improves reconciliation performance and availability (i.e. if a node fails, the activity it was executing is assigned to another available node).

With P2P-reconciler, data replication proceeds basically as follows. First, nodes execute local actions to update a replica of an object while respecting user-defined constraints. Then, these actions (with the associated constraints) are stored in the DHT based on the object’s identifier. Finally, reconciler nodes...
retrieve actions and constraints from the DHT and produce the global schedule, by reconciling conflicting actions in 6 distributed steps based on the application semantics. This schedule is locally executed at every node, thereby assuring eventual consistency [SBK04, SS05]. The replicated data is eventually consistent if, when all nodes stop the production of new actions, all nodes will eventually reach the same value in their local replicas.

In this protocol, we distinguish three types of nodes: the replica node, which holds a local replica; the reconciler node, which is a replica node that participates in distributed reconciliation; and the provider node, which is a node in the DHT that holds data consumed or produced by the reconcilers (e.g. the node that holds the schedule is called schedule provider).

We concentrate the reconciliation work in a subset of nodes (the reconciler nodes) in order to maximize performance. If we do not limit the number of reconcilers, the following problems take place. First, provider nodes and the network as a whole become overloaded due to a large number of messages aiming to access the same subset of DHT data in a very short time interval. Second, nodes with high-latencies and low-bandwidths can waste a lot of time with data transfer, thereby hurting the reconciliation response time. Our strategy does not create improper imbalances in the load of reconciler nodes since reconciliation activities are not computationally intensive.

2.3 Detailed presentation of P2P-reconciler

We now present P2P-reconciler in deeper detail. First, we introduce the reconciliation objects necessary for P2P-reconciler. Then, we describe the six steps of the reconciliation algorithm. Finally, we illustrate this algorithm at work over a Chord DHT.

2.3.1 Reconciliation objects

Data managed by P2P-reconciler during reconciliation are held by reconciliation objects that are stored in the DHT giving the object identifier. To enable the storage and retrieval of reconciliation objects, each reconciliation object has a unique identifier. P2P-reconciler uses the following reconciliation objects:

- **Action log** \( R \) (noted \( L_R \)): it holds all actions that try to update any replica of the object \( R \) (in the Example 2, all updates on \( T \)'s tuples performed on \( T_1, T_2 \text{ or } T_3 \) are stored in \( L_T \)). Notice that an action is first stored locally in the replica node and afterwards in the provider node that holds \( L_R \). In Example 2, only one action log is involved \( (L_T) \) because a single object is replicated \( (T) \). The action log makes up the input for reconciliation.

- **Clusters set** (noted \( CS \)): recall that a cluster contains a set of actions related by constraints, and can be ordered independently from other clusters when producing the global schedule. All clusters produced during reconciliation are stored in the clusters set reconciliation object.

- **Action summary** (noted \( AS \)): it captures semantic dependencies among actions, which are described by means of constraints. In addition, the action summary holds relationships between actions and clusters, so that each relationship describes an action membership (an action is a member of one or more clusters). An action membership is a pair of values \( (a_n, C_j) \), where \( a_n \) represents an action to be reconciled, and \( C_j \) indicates a cluster to which \( a_n \) belongs.

- **Schedule** (noted \( S \)): it contains an ordered list of actions, which is composed from the concatenation of clusters’ ordered actions. Thus, we denote a schedule reconciliation object as \( S = S_1 \oplus S_2 \ldots \oplus S_m \), where each \( S_i \) represents the sub-list of ordered actions coming from the cluster \( C_i \) and \( \oplus \) means concatenation.

Reconciliation objects are guaranteed to be available using known DHT replication solutions [APV07, KWR05]. P2P-reconciler’s liveness relies on the DHT liveness.
2.3.2 P2P-reconciler algorithm

P2P-reconciler executes reconciliation in 6 distributed steps as shown in Figure 1. Any connected node \( n \) can try to start reconciliation by inviting other available nodes to engage with it. Only one reconciliation can run at a time, thus if reconciliation is already running when \( n \) try to start it, \( n \) does not succeed and it must try again later. However, if \( n \) succeeds, the 1\textsuperscript{st} step (node allocation) allocates a subset of engaged nodes to step 2, another subset is allocated to step 3, and so forth until the 6\textsuperscript{th} step (details about node allocation are provided in the next sections). Nodes at step 2 start reconciliation. The output produced at each step becomes the input to the next one. In the following, we describe the activities performed in each step, and we illustrate parallel processing by explaining how these activities can be executed simultaneously by two reconciler nodes, \( n_1 \) and \( n_2 \).

![Figure 1. P2P-reconciler steps](image)

- **Step 1 – node allocation**: a subset of connected replica nodes is selected to proceed as reconciler nodes (detailed in Section 4).

- **Step 2 – actions grouping**: reconcilers take actions from the action log and put actions that try to update common object items into the same group. In Example 2, suppose that \( n_1 \) takes \( \{a_1^1, a_1^2\} \) and \( n_2, \{a_2^1, a_2^2\} \) as input. By hashing the identifiers of the replica items handled by these actions (respectively k1, k1, k1, and k2), \( n_1 \) puts \( a_1^1 \) and \( a_1^2 \) into the group \( G_1 \) (\( a_1^1 \) and \( a_2^1 \) handle the same object item identified by k1) whereas \( n_2 \) put \( a_2^1 \) into \( G_2 \) and \( a_2^1 \) into \( G_2 \) (\( a_2^1 \) and \( a_2^2 \) handle respectively the object items identified by k1 and k2). Thus, groups \( G_1 = \{a_1^1, a_2^1\} \) and \( G_2 = \{a_2^2\} \) are produced in parallel and are stored in the action log reconciliation object (L2). Clearly, in order to identify conflicting actions, we need to be able to distinguish object items from each other. This can be done by using keys or other means. For instance, two xml elements associated with different paths can be considered different object items. In this case, the element path works as an identifier. From the perspective of correctness, it does not matter if two distinct object items are considered the same object item by the reconciliation engine since the responsibility of judging conflicts is assigned to the application, which deeply knows the context. The responsibility of the reconciliation engine is to put together actions that are potentially in conflict. Of course, from the perspective of performance, the lack of a good strategy for differentiating object items can lead to larger clusters and, as a result, worse performance.

- **Step 3 – clusters creation**: reconcilers take action groups from the action log and split them into clusters of semantically dependent conflicting actions (two actions \( a_1 \) and \( a_2 \) are semantically independent if the application judges safe to execute them together, in any order, even if they update a common object item; otherwise, \( a_1 \) and \( a_2 \) are semantically dependent); system-defined constraints are created to represent the semantic dependencies detected in this step; these constraints and the action memberships that describe the association between actions and clusters are included in the action summary; clusters produced in this step are stored in the clusters set. In Example 2, consider that \( n_1 \) takes \( G_1 \) and \( n_2 \) takes \( G_2 \) as input. In this case, \( n_1 \) splits \( G_1 \) into clusters \( C_1 = \{a_1^1, a_2^1\} \) (a mutuallyExclusive\( (a_1^1, a_2^1) \)) system-defined constraint is produced to represent the semantic dependency between \( a_1^1 \) and \( a_2^1 \) and \( C_2 = \{a_2^2\} \) (\( a_2^2 \) tries to update the same object item as \( a_1^1 \) and \( a_2^1 \), but \( a_2^2 \) touches a distinct attribute, B; therefore, \( a_2^2 \) does not conflict with \( a_1^1 \) and \( a_2^1 \); at the same time, \( n_2 \) turns \( G_2 \) into cluster \( C_1 = \{a_2^2\} \). All these clusters are stored in the clusters set reconciliation object (CS). In addition, \( n_1 \) stores in the action summary (AS) the mutuallyExclusive\( (a_1^1, a_2^1) \) constraint and the fol-
lowing memberships: \{(a^{i}, C_{i}), (a^{j}, C_{i}), (a^{i}, C_{2})\}. Similarly, \(n_{2}\) stores in \(AS\) this set of memberships: \{(a^{j}, C_{i})\).

- **Step 4 – clusters extension:** user-defined constraints are not taken into account in clusters creation (e.g. although \(a^{i}\) and \(a^{j}\) belong to a parcel, the previous step does not put them into the same cluster, because they do not update a common object item). Thus, in this step, reconcilers extend clusters by adding to them new conflicting actions, according to user-defined constraints. These extensions lead to new relationships between actions and clusters, which are represented by new action memberships; the new memberships are included in the action summary. In Example 2, assume that \(n_{1}\) takes \(C_{i} = \{a^{i}, a^{j}\}\) as input whereas \(n_{2}\) takes \(C_{2} = \{a^{j}\}\) and \(C_{3} = \{a^{j}\}\) (each node deals with 2 actions). Then, \(n_{1}\) realizes that \(C_{i}\) does not need extensions, because its actions are not involved in user-defined constraints; in parallel, due to the parcel constraint, \(n_{2}\) extends \(C_{2}\) and \(C_{3}\) as follows: \(C_{2} \leftarrow C_{2} \cup \{a^{j}\}\), and \(C_{3} \leftarrow C_{3} \cup \{a^{j}\}\). In addition, \(n_{2}\) updates the action summary with these action memberships: \{(a^{j}, C_{2}), (a^{j}, C_{3})\}.

- **Step 5 – clusters integration:** clusters extensions lead to cluster overlapping (an overlap occurs when the intersection of two clusters results in a non-null set of actions); in this step, reconcilers bring together overlapping clusters. In Example 2, consider that \(n_{1}\) takes \{(a^{i}, C_{3}), (a^{j}, C_{i}), (a^{i}, C_{2}), (a^{j}, C_{3})\} as input whereas \(n_{2}\) takes \{(a^{i}, C_{i}), (a^{j}, C_{j})\}\) (each node deals with the memberships of 2 actions). Thus, \(n_{1}\) realizes that \(a^{i}\) is a member of \(C_{2}\) and \(C_{3}\), so \(n_{1}\) integrates them as follows: \(C_{2} \leftarrow C_{2} \cup C_{3} = \{a^{i}, a^{j}\}\); at the same time, \(n_{2}\) realizes that \(a^{i}\) and \(a^{j}\) have just one membership, so \(n_{2}\) does not perform integrations. At this point, clusters become mutually-independent, i.e. there are no constraints involving actions of distinct clusters.

- **Step 6 – clusters ordering:** in this step, reconcilers take clusters from the clusters set and order clusters’ actions; the ordered actions associated with each cluster are stored in the schedule reconciliation object (\(S\)); the concatenation of all clusters’ ordered actions makes up the global schedule that is executed by all replica nodes. In Example 2, suppose that \(n_{1}\) takes \(C_{i}\) as input whereas \(n_{2}\) takes \(C_{i}\). As a result, \(n_{1}\) produces the sub-list of ordered actions \(S_{i} = \{a^{i}\}\), because \(C_{i}\) actions are mutually exclusive; in parallel, \(n_{2}\) produces the sub-list of ordered actions \(S_{k} = \{a^{i}, a^{j}\}\), because \(C_{k}\) actions are involved in a parcel constraint. The global schedule is \(S \leftarrow S_{i} \oplus S_{k} = \{a^{i}, a^{j}, a^{j}\}\).

At every step, the P2P-reconciler algorithm takes advantage of data parallelism, i.e. several nodes perform simultaneously independent activities on a distinct subset of actions (e.g. ordering of different clusters). No centralized criterion is applied to partition actions. Indeed, whenever a set of reconciler nodes requests data from a provider, the provider node naïvely supplies reconcilers with about the same amount of data (the provider node knows the maximal number of reconcilers because it receives this information from the node that launches reconciliation).

![Figure 2. P2P-reconciler at work](image-url)
2.3.3 P2P-reconciler at work

We now illustrate the execution of the P2P-reconciler algorithm over a Chord DHT network. For simplicity, we consider only its first 3 steps and a few nodes at work. Figure 2 shows 8 nodes and their respective roles in the reconciliation protocol. All of them are replica nodes. Reconciliation objects are stored at provider nodes according to the hashed values associated with the reconciliation object identifiers (e.g., Chord maps a hashed value $v$ to the first node that has an identifier equal to or greater than $v$ in the circle of ordered node identifiers). In this example, we assume that Chord maps the hashed value of the action log identifier to node 1; using the same principle, the clusters set, the schedule and the action summary are mapped respectively to nodes 8, 12 and 15. Finally, node 9 is responsible for allocating reconcilers.

Any node can start the reconciliation by triggering the step 1 of P2P-reconciler at the appropriate node (e.g., node 9), which selects the best reconcilers and notifies them about the steps they should perform. In our example, node 9 selects node 2 to execute step 2, and it selects nodes 5 and 13 to perform step 3 (details about node allocation are provided in the next sections).

Node 2 starts the step 2 of reconciliation by retrieving actions from the action log (stored at node 1) in order to arrange them in groups of actions on common object items. At the same time, nodes 5 and 13 begin step 3 by requesting action groups to node 1; these requests are held in a queue at node 1 while action groups are under construction. When node 2 stores action groups at action log, node 1 replies the requests previously queued by nodes 5 and 13. At this moment, step 2 is terminated and step 3 proceeds. Notice that each reconciler works on independent data (e.g., nodes 5 and 13 receive distinct action groups from node 1). To assure this independence, provider nodes segment the data they hold based on the number of reconcilers (e.g., node 1 creates two segments of action groups, one for node 5 and another for node 13).

When step 2 terminates, nodes 5 and 13 receive action groups from node 1 and produce the corresponding clusters of actions, which are stored at node 8. In turn, node 8 replies requests for clusters that reconcilers of step 4 have previously queued; and so forth, until the end of step 6.

2.4 Dealing with dynamism

Whenever distributed reconciliation takes place, a set of nodes $N_d$ may be disconnected. As a result, the global schedule is not applied by nodes of $N_d$. Moreover, actions produced by $N_d$ nodes and not yet stored in the P2P network are not reconciled. In this subsection, we explain how P2P-reconciler assures eventual consistency despite disconnections. Fault-tolerance aspects are not studied in this paper since they are orthogonal to what is presented.

We need a new reconciliation object to assure eventual consistency in the presence of disconnections. Thus, we define schedule history, noted $H$, as a reconciliation object that stores a chronological sequence of schedules’ identifiers produced by reconciliations ($H = (S_{id_1}, ..., S_{id_n})$). A replica node can check whether it is up to date by comparing the identifier of the last schedule it has locally executed with $S_{id_n}$.

P2P-reconciler deals with dynamism as follows. Each node locally stores the identifier of the last schedule it has locally executed (noted $S_{last}$). In addition, every node knows the schedule history’s unique identifier. Thus, when a node $n$ of $N_d$ reconnects, it proceeds as follows: (1) $n$ checks whether $S_{last}$ is equal to $S_{id_n}$ and, if not (i.e., $n$’s replicas are out of date), $n$ locally applies all schedules that follow $S_{last}$ in history $H$; (2) actions locally produced by $n$ and not yet stored in the P2P network are put into the action log for later reconciliation.

3 DHT cost model

A DHT network is usually built on top of the Internet, which consists of nodes with variable latencies and bandwidths. As a result, the network costs involved in DHT data accesses may vary significantly from node to node and have a strong impact in the reconciliation performance. Thus, network costs should be considered to perform reconciliation efficiently. In this section, we propose a basic cost model for com-
puting communication costs in DHTs. On top of it, we can build customized cost models (e.g. we elaborated a customized cost model for selecting reconciler nodes to P2P-reconciler – Section 4).

In the basic cost model, we define communication costs (henceforth costs) in terms of latency and transfer times, and we assume links with variable latencies and bandwidths. In order to exploit bandwidth, the application behavior in terms of data transfer should be known. Since this behavior is application-specific, we exploit bandwidth in higher-level customized models.

Most DHT data access operations consist of a lookup for finding the address of the node $n$ that holds the requested information followed by direct communication with $n$ [HHLT’03]. In the lookup step, several hops may be performed according to nodes’ neighborhoods. Therefore, our DHT cost model relies on three metrics: lookup cost, direct cost, and transfer cost. The lookup cost, noted $lc(n, id)$, is the latency time spent in a lookup operation launched by node $n$ to find the data item identified by $id$. Similarly, direct cost, noted $dc(n_i, n_j)$, is the latency time spent by node $n_i$ to directly access $n_j$. And the transfer cost, noted $tc(n_i, n_j, d)$, is the time spent to transfer the data item $d$ from node $n_i$ to node $n_j$, which is computed based on $d$’s size and the bandwidth between $n_i$ and $n_j$.

### 3.1.1 Lookup cost

Lookup costs change dynamically as nodes join and leave the P2P network. In this subsection, we show how to compute lookup costs and deal with dynamic changes.

Node $n$ could easily compute the lookup cost $lc(n, id)$ by executing the lookup operation and measuring the associated time. However, this approach overloads the node that replies the lookup operation as it receives a lot of lookup messages. Furthermore, the network is overloaded. To avoid these problems, we propose that each node computes its lookup costs incrementally, by taking advantage of cost information held by its neighbors. With this approach, a node $n$ only keeps the lookup costs to a few of identifiers (i.e. one identifier for each reconciliation object); in addition, $n$ keeps the direct costs to a few of nodes (i.e. $n$’s neighbors). It would be unfeasible and not recommendable to keep information about the full identifier space or all nodes. Our approach is feasible because in a DHT a node $n$ looks for an identifier $id$ by communicating with the $n$’s neighbor that is closest to $id$.

We illustrate our solution with an example. In Figure 3a, let $n_2$ be a node that replies lookup operations searching for $id=x$; let arrows indicate the route of a lookup operation (e.g. if $n_2$ looks for $x$ it makes this route: $n_2 \rightarrow n_3 \rightarrow n_4$); let a number over an arrow be the latency between the associated nodes. In this example, the lookup cost $lc(n_2, x)$ is 100 (i.e. $40 + 60$), and $lc(n_1, x)$ is 150 (i.e. $50 + 40 + 60$). Instead of executing the lookup operation to compute $lc(n_1, x)$, $n_4$ can ask $n_3$ for $lc(n_2, x)$ and add to this cost the latency between $n_1$ and $n_2$ (i.e. $lc(n_1, x) = lc(n_2, x) + 50$). The advantage of this incremental approach is locality and to avoid network overload.

Join and leaves change the neighborhoods of nodes and, accordingly, the routes of lookup messages. As a result, lookup costs must be refreshed. However, we should avoid the refreshment at distant nodes to avoid network overload. To cope with this problem, we introduce two definitions:

- **Cost limit**: it is the maximal acceptable cost for looking up an identifier. The meaning of acceptable cost relies on the application on top of DHT. For instance, in the case of P2P-reconciler, which se-
lects a subset of replica nodes to proceed as reconciler nodes, it is not acceptable that the lookup cost of a particular reconciler overtakes the average lookup cost of the P2P network as a whole, because the number of reconcilers is usually much smaller than the number of replica nodes.

- **Relevant joins and leaves**: a join or leave is relevant for a node $n$ if it changes the cost for looking up an identifier in which $n$ is interested, such that the old or the new lookup cost does not overtake cost limit. Nodes refresh their lookup costs only in the presence of relevant joins and leaves.

We illustrate our approach for refreshing lookup costs with an example. In Figure 3b, let cost limit be 110; and consider that $n_5$ joins the DHT of Figure 3a taking the place of $n_3$ in the route towards $id=x$. The join of $n_5$ is relevant only to $n_2$ as $n_2$ updates $lc(n_2, x)$ from 100 (a value that does not overtake cost limit) to 120. In contrast, the join of $n_5$ is not relevant to $n_1$ and $n_4$ since the associated lookup costs remain unchanged. This join is not relevant to $n_1$ either, because both, the old lookup cost (i.e. 150) and the new one (i.e. 170), overtake cost limit. Thus, $n_1$, $n_3$ and $n_4$ do not participate in the refresh operation.

### 3.1.2 Direct cost

Direct costs change dynamically as nodes join and leave the P2P network. In this subsection, we show how to compute direct costs and deal with dynamic changes.

We first define $\text{home}(id)$ as the provider node that holds the identifier $id$. The direct cost $\text{dc}(n, \text{home}(id))$ represents the latency time spent by node $n$ to directly access $\text{home}(id)$. This cost can be exactly computed or estimated. With the exact approach, $n$ measures the latency between $n$ and $\text{home}(id)$. In contrast, with the estimated approach, $n$ measures the latencies between $n$ and a subset of nodes and then computes the corresponding average value, which represents the estimated latency between $n$ and $\text{home}(id)$. The exact approach is precise, but it can overload $\text{home}(id)$ as it becomes a central point of access for a lot of nodes. On the other hand, the estimated approach does not rely on accessing $\text{home}(id)$, thereby avoiding its overload, but it is not precise. We compare both approaches and, due to the small difference between the corresponding reconciliation times (i.e. 7%), we consider that the estimated approach should be employed in order to avoid overload.

Notice that the estimated approach requires a subset of nodes to estimate the latency between $n$ and $\text{home}(id)$. This subset should be $n$’s neighbors for DHTs whose neighborhoods do not rely on physical distances among nodes (e.g. Chord) since, in this case, estimation is not biased and the information needed is already available at $n$ (cost zero). However, if the DHT is location-aware, i.e. $n$’s neighbors are closer to $n$ than other nodes (e.g. CAN with design improvements), the use of $n$’s neighbors would lead to a biased estimation. Thus, in this case, the subset of nodes should be randomly selected from a bootstrap list (list of nodes that are likely connected).

Joins and leaves may change the $\text{home}(id)$. Thus, direct costs must also be refreshed. In our solution, $\text{dc}(n, \text{home}(id))$ is refreshed at node $n$ whenever $\text{home}(id)$ changes and the associated lookup cost (i.e. $lc(n, id)$) is smaller than the cost limit. To compute the refreshed value, we use the same strategy employed for computing the initial value. The principle of this approach is to avoid the execution of refreshment operations at far distant nodes, and its advantage is to avoid network overload.

### 4 P2P-reconciler node allocation

The first step of P2P-reconciler aims to select the best nodes to proceed as reconcilers in order to maximize performance. The number of reconcilers has a strong impact on the reconciliation time. Thus, this section concerns the estimation of the optimal number of reconcilers per step as well as the allocation of the best nodes. We first present how to determine the maximal number of reconciler nodes. Then, we introduce the P2P-reconciler cost model for computing the cost of each reconciliation step. Next, we describe how the cost provider node selects reconcilers based on P2P-reconciler cost model. Finally, we present our approach for managing the dynamic behavior of P2P-reconciler costs.
4.1 Determining the number of reconcilers

At the beginning of reconciliation, a subset of replica nodes must be allocated to P2P-reconciler steps in order to proceed as reconciler nodes. This allocation is dynamic as it depends on the reconciliation context (i.e. number of actions to be reconciled, network properties, etc.). Since P2P-reconciler is distributed, we can increase the number of reconciler nodes to reduce the reconciliation time. However, as we increase the number of reconcilers we also increase the number of exchanged messages and the work performed by provider nodes. As a result, beyond a given bound, increasing the number of reconcilers yields the opposite effect: the reconciliation time augments. In order to compute this bound, that represents the maximal number of reconcilers per step, we perform the following activities.

- First, we configure the reconciliation context by setting up some parameters (e.g. number of actions, number of connected replica nodes, number of reconciler nodes, minimal and maximal network latencies, network bandwidths), and then we simulate reconciliation several times, taking as a result a reconciliation sample. For each simulation, we change the topology of the physical and overlay networks or the set of actions to be reconciled or both, always respecting the parameters’ values. A simulation runs locally in a single node. An important aspect is that only network communication is simulated (everything else is done by the actual P2P-reconciler protocol).

- Second, we search an equation \( y = f(x) \) that describes the reconciliation behavior by performing a polynomial regression [KKMN98] with sample’s data. This equation allows us to forecast the reconciliation time of any reconciliation in the same context. The independent variable \( x \) is the number of reconciler nodes whereas the dependent variable \( y \) is the reconciliation time. We have always got an excellent correlation between \( x \) and \( y \) by using a polynomial of degree 3 as shown in Figure 4 (in Figure 4, \( r \) is the correlation coefficient and it can vary from 0 to 1; 1 denotes a perfect correlation).

- Third, we compute the derivative equation \( y' = f'(x) \); this derivative equation enables us to find which value of \( x \) produces the minimal value of \( y \). The point \((x, y)\) where \( y \) is minimal is called minimal point. Since \( f'(x) \) is a second-order polynomial as shown in Figure 4, the curve described by \( f(x) \) has exactly one minimal point and one maximum point, which correspond to the roots of \( f'(x) \).

- Finally, we calculate the minimal point, which represents the number of reconcilers that minimizes the reconciliation time in the given context. This optimal number of reconcilers is the same for every step. At the beginning of our research we tried to find a different number of reconcilers for each step, but we realized that, in practice, this approach did not improve our results. This can be explained by the trade-off between the providers’ workload and the network traffic. The best performance is achieved with a number of reconcilers that optimize the network traffic without overloading the provider nodes.

The larger the number of actions to be reconciled and the higher the network speed are, the larger the maximal number of reconcilers per step. In order to determine the number of reconcilers, we do not fix parameters like network bandwidth, latency, and others. Everything is variable. Regarding network bandwidth, we provide a list of possible values varying from 64 Kbps to 20 Mbps. The bandwidth values follow a Pareto distribution so that low bandwidths are more frequently assigned than high bandwidths. This means, the network topology of a single experiment has variable bandwidths. With respect to latencies, we provide the minimum and maximum latencies corresponding to the type of network we intend to simulate (e.g. Cluster, Grid, Internet, etc.) and, inspired by BRITE [Bri08], we place nodes in a 2-dimensional Cartesian coordinate space, called plane, so that the latency between two nodes \( n_i \) and \( n_j \) is proportional to the geometrical distance between \( n_i \) and \( n_j \) on the plane. This approach assures variable latencies among nodes. Details about our network simulator can be found in [Sim07].

We address the problem of obtaining sufficient samples by relying on peers’ collaboration. In [Mar07] we show that the only information needed to compute the maximal number of reconcilers per step is the equation \( y' = f'(x) \); after determining this equation, sample’s data are disposable. Therefore, in
order to obtain this equation, a node \( n \) proceeds as follows. First, \( n \) locally looks for an existing equation that corresponds to its need. If \( n \) does not succeed, \( n \) requests the equation’s coefficients from its neighbors. If no neighbor can provide this information, \( n \) locally produces a reconciliation sample and computes the associated equation, which is stored at \( n \) for future reuse. With time, a lot of samples are produced and the associated equations are shared among peers. As a result, the simulation is often avoided and, in this case, there is no overhead. For this reason, we did not consider integrating the simulation costs into global reconciliation cost. Our experiments have shown that the time needed to produce a complete sample and compute the associated equation varies from 20s to 60s depending on the number of actions to be reconciled.

$$y = -0.00035x^3 + 0.237x^2 - 37.887x + 3551.567$$

$$y' = -0.0011x^2 + 0.4741x - 37.8870$$

(a) High-speed network

$$y = -0.026x^3 + 0.985x^2 - 6.740x + 70.803$$

$$y' = -0.078x^2 + 1.970x - 6.740$$

(b) Low-speed network

Figure 4. Examples of polynomial regression

Finally, the relationship between the increase on the provider/reconciler interactions and the optimal number of reconcilers is not straightforward. It depends on the processing power of provider nodes, the amount of data to be transferred, the subjacent bandwidths and latencies, and so forth. However, it is very difficult to compute the optimal number of reconcilers analytically. Therefore, we decided to take advantage of simulation by producing a powerful simulator, which works with variable bandwidths, latencies, number of nodes, and data transfer sizes. In addition, our simulator is very easy to configure.

### 4.2 P2P-reconciler cost model

The P2P-reconciler cost model is built on top of the DHT cost model by taking into account each reconciliation step and defining a new metrics: node step cost. The node step cost, noted \( \text{cost}(i, n) \), is the sum of lookup, direct access, and transfer costs estimated by node \( n \) for executing step \( i \) of P2P-reconciler algorithm.

By analyzing the P2P-reconciler behavior in terms of lookup, direct access, and data transfer operations at every step, we produced a cost formula for each step of P2P-reconciler, which are shown in Table 1. There is no formula associated with step 1 because it is not performed by reconciler nodes.

As an example, let us explain \( \text{cost}(2, n) \). In the second step of P2P-reconciler \((i=2)\), node \( n \) takes actions from the action log \( R(L_R) \) and arranges them in groups of actions that try to update common object items; these groups are stored at \( L_R \). Thus, the first term in the associated formula \( (lc(n,L_R)) \) represents the lookup cost for finding \( L_R \) provider. The second term \( (2 \times dc(n,n_{LR}) \) corresponds to the direct costs for taking actions from \( L_R \) provider (request and reply). The third term \( (tc(n_{LR}, n, actSet) \) stands for the transfer cost of the action set from \( n_{LR} \) to \( n \). The fourth term \( (lc(n,L_R)) \) represents the lookup cost for finding
again \( L_R \) provider. The fifth term \((dc(n, n_{LR}))\) corresponds to the direct cost for storing groups in \( L_R \) provider (only request). And the last term \((tc(n, n_{LR}, grpSet))\) stands for the transfer cost of the action groups produced in this step from \( n \) to \( n_{LR} \). Similarly, all formulas can be explained.

\[
\begin{array}{|c|c|}
\hline
\text{Step } i & \text{Cost}(i, n) \\
\hline
2 & lc(n, L_R) + 2 \times dc(n, n_{LR}) + tc(n, L_R, n, actSet) + lc(n, L_R) + dc(n, n_{LR}) + tc(n, n_{LR}, grpSet) \\
3 & lc(n, L_R) + 3 \times dc(n, n_{LR}) + tc(n, L_R, n, grpSet) + lc(n, CS) + 2 \times dc(n, n_{CS}) + tc(n, n_{CS}, [grpSet + cluIds]) + lc(n, AS) + dc(n, n_{CS}) + tc(n, n_{CS}, [actSet + mSet]) \\
4 & lc(n, CS) + 3 \times dc(n, n_{CS}) + tc(n, n_{CS}, n, cluSet) + 2 \times lc(n, AS) + 3 \times dc(n, n_{CS}) + tc(n, n_{CS}, mSet) \\
5 & lc(n, AS) + 3 \times dc(n, n_{CS}) + tc(n, AS, n, mSet) + lc(n, CS) + dc(n, n_{CS}) + tc(n, n_{CS}, ovCluSet) \\
6 & lc(n, CS) + 3 \times dc(n, n_{CS}) + tc(n, n_{CS}, itgCluSet) + lc(n, AS) + 2 \times dc(n, n_{CS}) + tc(n, n_{AS}, sumActSet) + lc(n, S) + dc(n, n_{S}) + tc(n, n_{S}, ordActSet) \\
\hline
\end{array}
\]

Table 1. P2P-reconciler cost model

### 4.3 Node allocation

Node allocation is the first step of P2P-reconciler protocol as shown in Figure 1. It aims to select for every succeeding step a set of reconciler nodes that can perform reconciliation with good performance. In this subsection, we define a new reconciliation object needed in node allocation, and then we describe how reconciler nodes are chosen, and we illustrate that with an example.

We define communication costs, noted \( CC \), as a reconciliation object that stores the node step costs estimated by every replica node and used to choose reconcilers before starting reconciliation.

The node that holds \( CC \) in the DHT at a given time is called cost provider, and it is responsible for allocating reconcilers. The allocation works as follows. Replica nodes locally estimate the costs for executing every P2P-reconciler step, according to the P2P-reconciler cost model, and provide this information to the cost provider. The node that starts reconciliation computes the maximal number of reconcilers per step \((maxRec)\), as described in Section 4.1, and asks the cost provider for allocating at most \( maxRec \) reconciler nodes per P2P-reconciler step. As a result, the cost provider selects the best nodes for each step and notifies these nodes of the P2P-reconciler steps they should execute.

In our solution, the cost management is done in parallel with reconciliation. Moreover, it is network optimized since replica nodes do not send messages to the cost provider, informing about their estimated costs, if the node step costs overtake the cost limit. For these reasons, the cost provider does not become a bottleneck.

We now illustrate the allocation algorithm using an example. Table 2 shows the lookup and direct costs of 4 nodes belonging to a Chord DHT network [SMKK+01] with 1024 connected nodes. In a DHT, a node that is close to a reconciliation object (e.g. \( n_0 \) is close to \( L_R \)) may be far distant of others (e.g. \( n_0 \) is far distant of \( CS \) and \( S \)). As a result, a node that is suitable for a P2P-reconciler step may not be worth in other steps. For this reason, every P2P-reconciler step has its own set of reconcilers.

Table 3 presents the transfer costs associated with the same nodes of Table 2. For simplicity, we assumed that all links between reconciler nodes and provider nodes have 1Mbps of bandwidth. The sizes of transferred data items are estimated based on the number of actions to be reconciled, the average action size, and the number of reconciler nodes. For space reasons, we do not detail this estimation.

Table 4 shows the estimated costs that the cost provider receives from the replica nodes. These costs are computed by applying on the P2P-reconciler cost model (Table 1) the lookup and direct costs of the DHT cost model (Table 2) and the transfer costs (Table 3). We show in bold the less expensive cost associated with each P2P-reconciler step. Thus, in our example, if the maximal number of reconcilers per step is 1, the cost provider selects as reconciler for each P2P-reconciler step the node of Table 4 whose cost is in bold (i.e. \( Step_2 = \{ n_0 \} \), \( Step_3 = \{ n_0 \} \), \( Step_4 = \{ n_1 \} \), \( Step_5 = \{ n_2 \} \), \( Step_6 = \{ n_3 \} \)), and notifies its decision to these nodes.

Table 4. Node step costs

4.4 Managing the dynamic costs

The costs estimated by replica nodes for executing P2P-reconciler steps change as a result of disconnections and reconnections. To cope with this dynamic behavior and assure reliable cost estimations, a replica node \(n_i\) works as follows:

- **Initialization:** whenever \(n_i\) joins the system, \(n_i\) estimates its costs for executing every P2P-reconciler step. If these costs do not overtake the cost limit, \(n_i\) supplies the cost provider with this information.

- **Refreshment:** while \(n_i\) is connected, the join or leave of another node \(n_j\) may invalidate \(n_i\)'s estimated costs due to routing changes. Thus, if the join or leave of \(n_j\) is relevant to \(n_i\), \(n_i\) recomputes its P2P-reconciler estimated costs and refreshes them at the cost provider.
- **Termination**: when node leaves the system, if its P2P-reconciler estimated costs are smaller than the cost limit (i.e. the cost provider holds node’s estimated costs), node notifies its departure to the cost provider.

- **Crash**: two actions follow the crash of a node from the perspective of cost management. First, the cost provider discards the node estimated costs. This happens either as a result of an unsuccessful attempt of allocating node or due to the expiration of the validity of the node estimation (the cost provider associates a time to live with each cost estimation). Second, each node that has node as neighbor realizes the node absence recomputes node’s estimated costs, if necessary. This computation is required if and only if node looks for some reconciliation object by routing lookup operations through node. In this case, node additionally propagates the refreshed costs to its neighbors.

P2P-reconciler computes the cost limit based on these parameters: the expected average latency of the network (e.g. 150 ms for the Internet), and the expected average number of hops to lookup a reconciliation object (e.g. log(n)/2 for a Chord DHT, where n represents the number of connected nodes and can be established as 15% of the community size).

## 5 P2P-reconciler-TA protocol

P2P-reconciler-TA is a distributed protocol for reconciling conflicting updates in topology-aware P2P networks. Given a set of nodes, we exploit topological information to select the “best” nodes to participate in the different steps of an algorithm, in a way that achieves an optimal performance. A P2P network is classified as topology-aware if its topology is established by taking into account the physical distance among nodes (e.g. in terms of latency times).

Several topology-aware P2P networks could be used to validate our approach such as Pastry [RD01a], Tapestry [ZHSR+04, ZKJ01], CAN [RFHK+01], etc. We chose to construct our P2P-reconciler-TA over optimized CAN because it allows building the topology-aware overlay network in a relatively simple manner. In addition, its routing mechanism is easy to implement, although less efficient than other topology-aware P2P networks (e.g. the average routing path length in CAN is usually greater than in other structured P2P networks).

Basic CAN [RFHK+01] is a virtual Cartesian coordinate space to store and retrieve data as (key, value) pairs. At any point in time, the entire coordinate space is dynamically partitioned among all nodes in the system, so that each node owns a distinct zone that represents a segment of the entire space. To store (or retrieve) a pair \((k_1, v_1)\), key \(k_1\) is deterministically mapped onto a point \(P\) in the coordinate space using a uniform hash function, and then \((k_1, v_1)\) is stored at the node that owns the zone to which \(P\) belongs. Intuitively, routing in CAN works by following the straight line path through the Cartesian space from source to destination coordinates.

Optimized CAN aims at constructing its logical space in a way that reflects the topology of the underlying network. It assumes the existence of well-known landmarks spread across the network. A node measures its round-trip time to the set of landmarks and orders them by increasing latency (i.e. network distance). The coordinate space is divided into bins such that each possible landmarks ordering is represented by a bin. Physically close nodes are likely to have the same ordering and hence will belong to the same bin.

We claim that the switch from Chord (P2P-reconciler) to CAN (P2P-reconciler-TA) does not invalidate our results based on the following argument. The most important DHT property in our experiments from the perspective of performance is the average number of hops needed to find the node that holds a given key. Let \(N\) be the number of connected nodes and \(d\) be the number of dimensions into which the \(d\)-
dimensional CAN space is divided. Chord requires \((\log N)/2\) hops on average to find a key whereas CAN needs \((d/4)(N^{1/d})\) hops on average. Since \(d=2\) in our experiments, \((\log N)/2 < (N^{1/2})/2\). That means, due to the need of a larger number of hops to find a key over CAN, the expected performance over CAN is worse than Chord. This fact makes our results still better.

Briefly, P2P-reconciler-TA works as follows. Based on the network topology, it selects the best provider and reconciler nodes. These nodes then reconcile conflicting updates and produce a schedule, which is an ordered list of non-conflicting updates. In this work, we focus on node allocation by proposing a dynamic distributed algorithm for efficiently selecting provider and reconciler nodes. We first introduce some definitions, and then we present the allocation algorithm in detail.

5.1 Definitions

P2P-reconciler-TA uses the following reconciliation objects: action log \((L_R)\), action summary \((AS)\), clusters set \((CS)\), and schedule \((S)\). The action log contains update actions to be reconciled; the action summary holds constraints among actions; the clusters set stores clusters of conflicting actions; and the schedule holds an ordered list of actions that do not violate constraints. For availability reasons, we produce \(k\) replicas of each reconciliation object and store these replicas into different providers. We note these terms as follows:

- \(RO\): set of reconciliation objects \(\{L_R, AS, CS, S\}\).
- \(ro\): a reconciliation object belonging to \(RO\) (e.g. \(CS\), \(L_R\), etc.).
- \(ro_i\): the replica \(i\) of the reconciliation object \(ro\) (e.g. \(CS_1\) is the replica \(1\) of \(CS\)), where \(1 \leq i \leq k\); the coordinates \((x_i, y_i)\) are associated with \(ro_i\) and determines the \(ro_i\) placement over the CAN coordinate space; \(ro_i\) is stored at the provider node \(p_{roi}\) whose zone includes \((x_i, y_i)\).
- \(P_{ro}\): set of \(k\) providers \(p_{roi}\) that store replicas of the reconciliation object \(ro\).
- \(best(P_{ro})\): the most efficient provider node holding a replica of \(ro\).

We apply various criteria to select the best provider nodes. One of such criteria establishes that a provider node should not be isolated in the network, i.e. it should be close to a certain number of neighbors that can become reconcilers, and therefore are called potential reconcilers. The physical proximity in terms of latency is not enough; a potential reconciler should also be able to access provider’s data by an acceptable cost. Thus, such a potential reconciler is considered a good neighbor of the associated provider node. We now present metrics and terms applied in provider node selection:

- \(accessCost(n, p)\): the cost for a node \(n\) accessing data stored at the provider node \(p\) in terms of latency and transfer times. The transfer time relies on the message size, which is usually variable. For simplicity, we consider a message of fixed size (e.g. 4 Kb). Equation 1 shows that the \(accessCost(n, p)\) is computed as the latency between \(n\) and \(p\) (noted \(latency(n, p)\)) plus the time to transfer the message \(msg\) from \(p\) to \(n\) (noted \(tc(p, n, msg)\)).

\[
accessCost(n, p) = latency(n, p) + tc(p, n, msg)
\]  

- \(maxAccessCost\): the maximal acceptable cost for any node accessing data stored in provider nodes; if \(accessCost(n, p) > maxAccessCost\), \(n\) is considered far away from \(p\), and therefore it is not a good neighbor of \(p\).
- \(potRec(p)\): number of potential reconcilers that are good neighbors of \(p\).
- \(minPotRec\): minimal number of potential reconcilers required around a provider node \(p\) in order to accept \(p\) as a candidate provider; if \(potRec(p) < minPotRec\), \(p\) is considered isolated in the network.
- **candidate provider**: any provider node \( p \) with \( \text{potRec}(p) \geq \text{minPotRec} \) is considered a candidate in the provider selection.

- **cost provider**: node that stores costs used in the node selection.

- **QoN(p)**: quality of network around the provider node \( p \). It is defined as the average access cost associate with good neighbors of \( p \), and it is computed by equation 2. In this equation, \( n_i \) represents a good neighbor of \( p \).

\[
\text{QoN}(p) = \frac{1}{\text{potRec}(p)} \sum_{i=1}^{\text{potRec}(p)} \text{accessCost}(n_i, p)
\]  

(2)

Another criterion for selecting a provider node is its proximity to other providers. During a reconciliation step, a reconciler node often needs to access various reconciliation objects. By approximating provider nodes we reduce the associated access costs. We now present some terminology for reconciler selection:

- **candidate reconcilers**: set of nodes that are candidate to become reconcilers. This set includes all good neighbors of selected providers.

- **step**: a reconciliation stage.

### 5.2 Detailed algorithm

P2P-reconciler-TA selects provider nodes and candidate reconcilers as follows. Every provider node regularly evaluates its network quality and, according to the number of potential reconcilers around it, the provider announces or cancels its candidature to the cost provider node. The cost provider, in turn, manages candidatures by monitoring which providers have the best network quality. Whenever the best providers change, the cost provider performs a new selection and notifies its decision to provider nodes. Following this notification, provider nodes inform their good neighbors whether they are candidate reconcilers or not. With the selection of new providers, current estimated reconciliation costs are discarded and new estimations are produced by the new candidate reconcilers. Thus, selected provider nodes and candidate reconcilers are dynamically changing according to the evolution of the network topology. We now detail each step of node allocation.

#### 5.2.1 Computing provider node’s QoN

A provider node computes its network quality by using equation 2 and the input data supplied by its good neighbors. Good neighbors introduce themselves to the provider nodes as follows. Consider that node \( n \) has just joined the network. For each reconciliation object \( ro \in RO \), \( n \) looks for the closest node that can provide \( ro \), noted \( p_{ro} \), and if \( \text{accessCost}(n, p_{ro}) \) is acceptable, \( n \) introduces itself to \( p_{ro} \) as a good neighbor by informing \( \text{accessCost}(n, p_{ro}) \). Node \( n \) finds the closest \( p_{ro} \) as follows. First, \( n \) uses \( k \) hash functions to obtain the \( k \) coordinates \((x_i, y_i)\) corresponding to each replica \( ro_i \). Then, \( n \) computes the Cartesian distance between \( n \’s \) coordinates and each \((x_i, y_i)\). Finally, the closest \( p_{ro} \) is the one whose zone includes the closest \((x_i, y_i)\) coordinates. The closest \( p_{ro} \) is called the \( n \’s \) reference provider wrt. \( ro \). Figure 5 illustrates how node \( n \) finds its reference provider wrt. the action summary reconciliation object (AS).

Provider nodes and the associated potential reconcilers cope with the dynamic behavior of the P2P network as follows. A provider node dynamically refreshes its QoN based on its good neighbors’ joins, leaves, and failures. Joins and leaves are notified by the good neighbors whereas failures are detected by the provider node based on the expiration of a \( \text{ttl} \) (time-to-live) field. On the other hand, a good neighbor dynamically changes a reference provider \( p_{ro} \) whenever \( p_{ro} \) gives up the responsibility for \( ro \). If \( p_{ro} \) disconnects or transfers \( ro \) to another provider, \( p_{ro} \) notifies these events to its good neighbors. However, if \( p_{ro} \) fails its good neighbors detect such failure and change the corresponding reference provider.
5.2.2 Managing provider candidature

The network quality associated with a provider node dynamically changes as its potential reconcilers join, leave, or fail. Thus, a provider node often refreshes its candidature as follows. When the neighborhood situation of a provider $p$ switches from isolated (i.e. $p$ has a few of potential reconcilers around it) to surrounded (i.e. $\text{potRec}(p) \geq \text{minPotRec}$) $p$ announces its candidature to the cost provider. In contrast, when $p$ switches from surrounded to isolated, $p$ cancels its candidature. Finally, if $p$’s $QoN$ varies while it remains surrounded of potential reconcilers, $p$ updates its $QoN$. Figure 6 illustrates $AS$ candidate providers for $\text{minPotRec} = 4$. Since we replicate reconciliation objects, we assume that at least one provider node is available for each reconciliation object. In [Mar07], we prove that our solution assures high availability of replicated objects in the DHT.

5.2.3 Selecting provider nodes

For each reconciliation object, P2P-reconciler-TA must select the best provider node. This selection should take into account the proximity among providers since different providers are accessed in the same reconciliation step. We reduce the search space of best providers by applying the heuristic illustrated in Figure 7. First, we select the $\text{best}(P_{AS})$ and the $\text{best}(P_{CS})$ (Figure 7a). These nodes must be as close as possible from each other because $AS$ and $CS$ are the most accessed reconciliation objects and both are often retrieved in the same step. Next, we select the $\text{best}(P_{LR})$ and the $\text{best}(P_{S})$ based on the pair ($\text{best}(P_{AS}), \text{best}(P_{CS})$) previously selected (Figure 7b); $\text{best}(P_{LR})$ must be as close as possible to the $\text{best}(P_{AS})$ since a reconciler accesses both $\text{best}(P_{LR})$ and $\text{best}(P_{AS})$ in the same step whereas $\text{best}(P_{S})$ must be as close as possible to the $\text{best}(P_{CS})$ for the same reason. Figure 7c shows the selected providers of our illustrative scenario (i.e. $P_{AS1}, P_{CS3}, P_{S1}$, and $P_{LR5}$).

The candidate providers filtered to participate of the provider selection vary with time. To face this dynamic behavior of candidatures, the cost provider automatically launches a new provider selection whenever the set of filtered candidates changes.

5.2.4 Notifying provider selection

Changing the selected provider leads to changes in the set of candidate reconcilers and invalidates all estimated reconciliation costs. As a result, the cost provider discards estimated costs and notifies the result of provider selection to provider nodes. The provider nodes, in turn, proceed as follows. If the provider $p$ switches from selected to unselected, $p$ notifies its good neighbors that from now on they are no longer candidate reconcilers. In contrast, if the provider $p$ switches from unselected to selected, $p$ notifies its good neighbors that from now on they are candidate reconcilers.

---

**Figure 5.** Finding the $AS$ reference provider  
**Figure 6.** Managing provider candidature
6 Validation

We validated and evaluated the performance of our reconciliation solutions through experimentation and simulation. The experimentation over Grid5000 (see Annex A) was useful to validate the algorithms and calibrate our simulator. The simulator allowed us to scale up to higher numbers of nodes. In this section, we first introduce our performance model, and then we report the main performance evaluation results. In [Sim07], we describe in detail how we simulate large P2P networks.

6.1 Performance model

We evaluated the performance of P2P-reconciler, and P2P-reconciler-TA. Our performance model takes into account the strategy for selecting provider and reconciler nodes, the action log size (i.e. the number of actions to be reconciled), and the network topology. Some parameters are applicable to all evaluated algorithms whereas other parameters are protocol-specific. Table 5 summarizes such parameters arranging them in three groups: general parameters, parameters that are specific for the P2P-reconciler protocol, and parameters specific for P2P-reconciler-TA.

In all experiments, we need to determine the number of actions to be reconciled, noted \( Nb-\text{Actions} \). The network topology must also be set before any experiment. The network topology is defined by the number of connected nodes, noted \( Nb-\text{Nodes} \), the bandwidth of the links among these nodes, noted \( \text{Bandwidth} \), the average link latency, noted \( \text{Avg-Latency} \), and the associated standard deviation, noted \( \text{Sd-Latency} \). Indeed, we provide the minimal and maximal latencies corresponding to the type of network we intend to simulate (e.g. cluster, Grid, Internet, etc.), and after the node placement we compute the resulting average latency and the associate standard deviation. For topologies with variable bandwidths, the bandwidth values follow a Pareto distribution (low bandwidths are more frequently assigned than high bandwidths). We chose the Pareto distribution because it models more realistically the distribution of bandwidths in which the number of sites with higher bandwidths decreases exponentially. We produced 3 different networks for each set of parameter values. We also produced 3 action logs for each action log size. By combining different action logs with different networks for the same set of parameter values, we generate several distinct reconciliation scenarios that avoid over fitted results.

The P2P-reconciler protocol has only one specific parameter, namely the strategy for selecting reconciler nodes; this parameter is called \( \text{Allocation} \). We define three allocation strategies: random selection (RDM); cost-based selection using precise costs for direct communication (CB/P); and cost-based selection using estimated costs for direct communication (CB/E). Recall from Section 3 that the precise approach may overload provider nodes and the network as a whole whereas the estimated approach, although not precise, avoids overloads. For every allocation strategy, all experiments use the optimal number of reconcilers.

The P2P-reconciler-TA protocol has specific parameters for node allocation and network simulation. Concerning node allocation, three strategies are possible: random selection of provider and reconciler...
nodes (RDM), cost-based selection of reconciler nodes only (REC), and cost-based selection of both provider and reconciler nodes (PRV-REC). Recall from Section 5 that we replicate each reconciliation object to assure high availability. Hence, each reconciliation object has various candidate provider nodes. In the latter allocation strategy (i.e. PRV-REC), the parameter $\text{Nb-Providers}$ specifies how many candidate providers should be considered for each reconciliation object in order to select an efficient set of provider nodes. We adopt such a heuristic approach to reduce the search space, thereby avoiding an exhaustive search.

We based our performance evaluation on the IceCube’s benchmark [PSM02, PSM03] and we set up application parameters as IceCube. In short, the benchmark is based on a calendar application which consists of an appointment database shared by multiple users. User commands may request a meeting, possibly proposing several alternative times, and cancel a previous request. Database-level actions add or remove a single appointment. The user-level request command is mapped onto an alternative constraint containing a set of add actions; similarly for cancel. Each such action contains the time, duration, participants and location of the proposed appointment. The calendar inputs are based on traces from actual Outlook calendar. This was artificially scaled up in size, and were modified to contain conflicts and alternatives and to control the difficulty of reconciliation.

We have shown in [MAPV06] that if we run our P2P reconciliation approach over a high-speed network we improve the reconciliation performance with respect to the centralized counterpart (i.e. IceCube). However, the focus of our work is to provide high data availability in a P2P scenario where individual sites are not very reliable and might be disconnected for variable periods of time, with good scalability, acceptable performance, and limited overhead. We have not aimed to achieve optimal performance in any scenario since this might be unfeasible. Since a P2P network usually has a large number of connected nodes which can leave at any time, in the P2P scenario, availability and scalability are the most important properties as far as a reasonable performance is provided.

**Table 5. Evaluation parameters**

### 6.2 Experimental results

We now present our main experimental results. We first show the performance of the P2P-reconciler protocol. Then, we present the evaluation of the P2P-reconciler-TA protocol.

The first experiment aims to evaluate the behavior of the cost-based approach as the number of actions increases. In this evaluation, we configured the network with variable latencies, constant bandwidth (1 Mbps), and 1024 connect nodes. The number of actions varies from $10^6$ to $10^5$. Figure 8 shows that the reconciliation time using cost-based selection of reconciler nodes (CB/P-1-1024) remains advantageous wrt. the random approach (RDM-1-1024) as the number of actions increases.

The second experiment studies the reconciliation performance with variable bandwidths. Values between 64Kbps and 20 Mbps were assigned to connected nodes according to the Pareto distribution (low bandwidths are more frequently assigned than high bandwidths). We also varied the number of actions to be reconciled in order to observe the scalability of P2P-reconciler. Figure 9 shows that the inclusion of transfer costs in the P2P-reconciler cost model is advantageous in scenarios with variable bandwidths, as
is the case of the Internet. The performance improvement provided by the cost-based approaches (CB/P 1024 and CB/E 1024) wrt. the random approach (RDM 1024) achieved a factor of 26 in Figure 9; recall that in Figure 8 we show the same performance improvement varying only latencies, and the corresponding factor is 1.6. The scalability also improved since in Figure 9 the reconciliation times using cost-based approaches (CB/P 1024 and CB/E 1024) are represented by straight lines. In addition, the performance of the precise and the estimated cost-based approaches are quite similar (although the corresponding lines overlap in the scale of Figure 9, there is a difference of about 10%).

Finally, we deepen the investigation of P2P-reconciler scalability by means of two experiments. In the first one, we studied the impact of the number of connected nodes on the reconciliation time (the larger the number of nodes is, the larger the average number of hops to lookup an identifier in the DHT). The network had variable latencies and bandwidths; 10,000 actions were reconciled. We varied the number of connected nodes from 1024 to 32768. Recall from the motivating application (i.e. the P2P Wiki) that, although the number of users updating a single data object in parallel is usually small, the size of the collaborative network to which this object belongs may be large. Figure 10 represents the reconciliation time with a straight line, which means an excellent scalability wrt. the number of connected nodes. In the second experiment, we studied the impact of the action size on the reconciliation time, by varying it from 10 bytes to 1024 bytes. Figure 11 shows that this result is also quite good since an increase of two orders of magnitude on the action size produced a corresponding increase of about 2.6 times on the reconciliation time (from 20s to 52s).

Liveness is an important issue in dynamic systems. P2P-reconciler provides a greater degree of availability, scalability and fault-tolerance than the centralized solution. In addition, the performance of P2P-reconciler is good since it takes 20s to reconcile 10,000 actions in a network with variable latencies and bandwidths (recall that P2P-reconciler depends on network communication). The centralized solution is unsuitable for P2P networks due to its low availability in dynamic environments.

We now present performance results concerning the P2P-reconciler-TA protocol. The first experiment aims to observe the scalability of P2P-reconciler-TA by studying the impact of the number of connected nodes on the reconciliation time (the larger the number of nodes is, the larger the average number of hops needed to lookup an identifier in the DHT). We configured the network with variable bandwidths and we varied the number of connected nodes (Nb-Nodes) from 1024 to 4096. The number of reconciled actions (Nb-Actions) was 1005. Erro! A origem da referência não foi encontrada. represents the reconciliation time with a straight line, which means an excellent scalability wrt. the number of connected nodes.

Recall from Section 5 that reconciliation objects are replicated and stored in the DHT according to multiple hash functions in order to assure high availability. As a result, for each reconciliation object, P2P-reconciler-TA must select the best provider node. Despite the limited number of replicas (typically around 10) the search space is quite large since the combination of provider nodes must be taken into account. We aim at drastically reducing the search space of best providers while preserving the best alternatives in the reduced search space. This allows us to efficiently select provider nodes. So, our second experiment studies the selection of provider nodes by varying the number of candidate providers per reconciliation object. The candidates are chosen according to their network quality (the network quality around the provider node $p$ is defined as the average access cost, in terms of latency and transfer times, associated with $p$’s neighbors that are closest to $p$). Erro! A origem da referência não foi encontrada. shows that our heuristic achieves the best performance with small numbers of candidates (Nb-Providers = 3 or 4). This is an excellent result since the smaller the number of candidates is, the smaller the search space (e.g. Nb-Providers = 3 with 4 involved reconciliation objects results a search space of size $3^4 = 81$).
The main motivation for proposing P2P-reconciler-TA is to improve the performance of P2P-reconciler by taking advantage of topology-aware networks. Thus, our last experiment compares the performance of P2P-reconciler and P2P-reconciler-TA while running both protocols in the same context (i.e. number of actions to reconcile, number of connected nodes, network bandwidths and latencies, etc.). Figure 14 shows that P2P-reconciler-TA over CAN outperforms P2P-reconciler by a factor of 2 (i.e. a performance improvement of 50%). This is an excellent result if we consider that P2P-reconciler is already an efficient protocol and CAN is not the most efficient topology-aware P2P network (e.g. Pastry and Tapestry are more efficient than CAN).
7 Related work

In the context of P2P networks, there has been little work on managing data replication in the presence of updates. Most of data sharing P2P networks consider the data they provide to be very static or even read-only. Freenet [CMHS’02] partially addresses updates which are propagated from the updating peer downward to close peers that are connected. However, peers that are disconnected do not get updated. P-Grid [ACDD’03, AHA03] is a structured P2P network that exploits epidemic algorithms to address updates. It assumes that conflicts are rare and their resolution is not necessary in general. In addition, P-Grid assumes that probabilistic guarantees instead of strict consistency are sufficient. Moreover, it only considers updates at the file level. In OceanStore [KBCC’00] every update creates a new version of the data object. Consistency is achieved by a two-tiered architecture: a client sends an update to the object’s primary copies and some secondary replicas in parallel. Once the update is committed, the primary copies multicast the result of the update down the dissemination tree. OceanStore assumes an infrastructure comprised of servers that are connected by high-speed links. Different from the previous works, we propose to distribute the reconciliation engine in order to provide high availability.

Table 6 compares the replication solutions provided by different types of P2P systems. Clearly, none of them provide eventual consistency among replicas along with weak network assumptions, which is the main concern of this work.

The distributed log-based reconciliation algorithms proposed by Chong and Hamadi [CH06] addresses most of our requirements, but this solution is unsuitable for P2P systems as it does not take into account the dynamic behavior of peers and network limitations. Operational transformation [VCFS00] also addresses eventual consistency among replicas, but this approach is specific for collaborative edition and it assumes synchronous collaboration (i.e. concurrent updates of replicas). Our approach assures eventual consistency among replicas, which enables asynchronous collaboration among users. In addition, we provide multi-master replication and we do not assume servers linked by high-speed links.

In the context of APPA (Atlas Peer-to-Peer Architecture), a P2P data management system which we are building [AMPV06b, MAPV06], we proposed the DSR-cluster algorithm [MPJV06, MPV05], a distributed version of the semantic reconciliation engine of IceCube [KRSD01, PSM03] for cluster networks. However, DSR-cluster does not take into account network costs during reconciliation. A fundamental assumption behind DSR-cluster is that the communication costs among cluster nodes are negligible. This assumption is not appropriate for P2P systems, which are usually built on top of the Internet. In this case, network costs may vary significantly from node to node and have a strong impact on the performance of reconciliation.

### 8 Conclusion

In this paper, we proposed the P2P-reconciler, a distributed protocol for semantic reconciliation in P2P networks. Our main contributions are a cost model for computing communication costs in DHTs and an algorithm that takes into account these costs and the P2P-reconciler steps to select the best reconciler nodes. For computing communication costs, we use local information and we deal with the dynamic behavior of nodes. In addition, we limit the scope of event propagation (e.g. joins or leaves) in order to avoid network overload.

Furthermore, we proposed a topology-aware approach to improve response times in P2P distributed semantic reconciliation. The P2P-reconciler-TA algorithm dynamically takes into account the physical network topology combined with the DHT properties when executing reconciliation. We proposed topology-aware metrics and cost functions to be used for dynamically selecting the best nodes to execute reconciliation, while considering dynamic data placement.

We validated P2P-reconciler through implementation and simulation. The experimental results showed that our cost-based reconciliation outperforms the random approach by a factor of 26. In addition, the number of connected nodes is not important to determine the reconciliation performance due to the DHT scalability and the fact that reconcilers are as close as possible to the reconciliation objects. The action size impacts the reconciliation time in a logarithmic scale. Compared with the centralized solution, which is more efficient but low available, our algorithm yields high data availability and excellent scalability, with acceptable performance and limited overhead.

In the same way, we also validated P2P-reconciler-TA. The experimental results show that our topology-aware approach achieves a performance improvement of 50% in comparison with the P2P-reconciler. In addition, P2P-reconciler-TA has proved to be scalable with limited overhead and thereby suitable for P2P environments. Our topology-aware approach is conceived for distributed reconciliation; however, our metrics, costs functions as well as our selection approach are useful in several contexts.

ANNEX A: REPLICATION SUPPORT IN APPA

We propose a solution for data replication in P2P networks that assures eventual consistency among replicas. Such solution is built in the context of APPA (Atlas Peer-to-Peer Architecture). APPA is a data management system that provides scalability, availability and performance for P2P advanced applications, which must deal with semantically rich data (e.g. XML documents, relational tables, etc.) using a high-level SQL-like query language. The replication service is placed in the upper layer of APPA architecture; the APPA architecture provides an application programming interface (API) to make it easy for P2P collaborative applications to take advantage of data replication. The architecture design also establishes the integration of the replication service with other APPA services by means of service interfaces.

This section introduces the APPA architecture, and then describes the proposed APPA replication service.

APPA

APPA has a layered service-based architecture. Besides the traditional advantages of using services (encapsulation, reuse, portability, etc.), this enables APPA to be network-independent so it can be implemented over different structured (e.g. DHT) and super-peer P2P networks. The main reason for this choice is to be able to exploit rapid and continuing progress in P2P networks. Another reason is that it is unlikely that a single P2P network design will be able to address the specific requirements of many different applications. Obviously, different implementations will yield different trade-offs between performance, fault-tolerance, scalability, quality of service, etc. For instance, fault-tolerance can be higher in DHTs because no node is a single point of failure. On the other hand, through index servers, super-peer networks enable more efficient query processing. Furthermore, different P2P networks could be combined in order to exploit their relative advantages, e.g. DHT for key-based search and super-peer for more complex searching.

This section introduces the APPA architecture, and then describes the proposed APPA replication service.

**P2P network services.** This layer provides network independence with services that are common to different P2P networks:

- **Peer id assignment:** assigns a unique id to a peer using a specific method, e.g. a combination of super-peer id and counter in a super-peer network.
- **Peer linking:** links a peer to some other peers, e.g. by locating a zone in CAN.
- **Key-based storage and retrieval (KSR):** stores and retrieves a \((key, object)\) pair in the P2P network, e.g. through hashing over all peers in DHT networks or using super-peers in super-peer networks. An important aspect of KSR is that it allows managing data using object semantic. Object semantic means that an object stored in the P2P network consists of a set of data attributes which can be accessed individually for read or write purposes. This approach is appropriate for optimizing object access performance since we do not need to transfer the entire object through the network at each object access operation as the existing P2P networks use to do.
- **Key-based time stamping (KTS):** generates monotonically increasing timestamps which are used for ordering the events occurred in the P2P system.
- **Peer communication:** enables peers to exchange messages (i.e. service calls).

**Basic services.** This layer provides elementary services for the advanced services using the P2P network layer:
- **Persistent data management (PDM):** provides high availability for the (key, object) pairs which are stored in the P2P network.

- **Communication cost management:** estimates the communication costs for accessing a set of objects that are stored in the P2P network. These costs are computed based on latencies and transfer rates, and they are refreshed according to the dynamic connections and disconnections of nodes.

- **Group management:** allows peers to join an abstract group, become members of the group and send and receive membership notifications. This is similar to group communication systems [CKV01, CJKR’03].

**Advanced services.** This layer provides advanced services for semantically rich data sharing including schema management, replication [APV07, EMP07, MAPV06, MP06, MPJV06], query processing [AMPV06b, APV06], security, etc. using the basic services.

**Figure 15.** APPA architecture

**DATA REPLICA TION IN APPA SYSTEM**

The APPA replication service [EMP07, MAPV06, MP06, MPJV06] is integrated to the PDM (Persistent Data Management) and KSR (Key-based Storage and Retrieval) services in order to store and retrieve data objects used during reconciliation in a highly available manner. PDM takes advantage of multiple hash functions to precisely place object replicas in the P2P network. With PDM, it is possible to implement the lock and unlock operations over a replicated (k, object) pair stored in the P2P network. In addition to PDM, the replication service is integrated to the CCM service (Communication Cost Management), which estimates the communication costs for accessing objects that are stored in the P2P network. These costs are estimated by taking into account latencies and transfer rates as well as the dynamic behavior of nodes that can join and leave the network at any time. The integration of APPA replication service with PDM and CCM is made by means of service interfaces.

In order to make it easy for P2P collaborative applications to take advantage of the APPA replication service, we have defined an application programming interface (API) that abstracts the APPA architecture and works as a façade for the APPA system as a whole by receiving service invocations and internally dispatching such invocations.

We proved the APPA’s network-independence by implementing APPA over a super-peer network (JXTA) and two distinct structured networks (Chord and CAN). JXTA provides a good support for the
APPA’s P2P Network services. The functionality provided by APPA’s peer id assignment, peer linking, and peer communication services are already available in the JXTA core layer. Thus, APPA simply uses JXTA’s corresponding functionality. In contrast, JXTA does not provide an equivalent service for key-based storage and retrieval (KSR). Thus, we implemented KSR on top of Meteor [Met06] which is an open-source JXTA service. APPA’s advanced services, like replication and query processing, are provided as JXTA community services. The key advantage of APPA implementation is that only its P2P network layer depends on the JXTA platform. Thus, APPA is portable and can be used over other platforms by replacing the services of the P2P network layer.

Chord [SMKK+01] and CAN (Content Addressable Network) [RFHK+01] are two of the most known DHTs. Chord is a simple and efficient DHT that can lookup a data, which is stored at some node in the network, in $O(\log n)$ routing hops, where $n$ is the number of nodes. Its lookup mechanism is probably robust in the face of frequent node failures and re-joins, and it can answer queries even if the system is continuously changing. CAN is based on a logical $d$-dimensional Cartesian coordinate space, which is partitioned into hyper-rectangles, called zones. Each node in the system is responsible for a zone. A data is hashed to a point in the coordinate space, and it is stored at the node whose zone contains the point’s coordinates. In CAN, a stored data can be retrieved in $O(dn^{1/d})$ where $n$ is the number of nodes.

The validation of the APPA replication service took place over the Grid5000 platform [Gri06]. Grid5000 aims at building a highly reconfigurable, controllable and monitorable experimental Grid platform, gathering 9 sites geographically distributed in France featuring a total of 5000 nodes. Within each site, the nodes are located in the same geographic area and communicate through Gigabit Ethernet links as clusters. Communications between clusters are made through the French academic network (RENER). Grid5000’s nodes are accessible through the OAR batch scheduler from a central user interface shared by all the users of the Grid. A cross-clusters super-batch system, OARGrid, is currently being deployed and tested. The home directories of the users are mounted with NFS on each of the infrastructure’s clusters. Data can thus be directly accessed inside a cluster. Data transfers between clusters have to be handled by the users. The storage capacity inside each cluster is a couple of hundreds of gigabytes. Now more than 600 nodes are involved in Grid5000. Additionally, in order to study the scalability of the APPA replication service with larger numbers of nodes that are connected by means of links with variable latencies and bandwidths, we implemented simulators using Java and SimJava [HM98], a process based discrete event simulation package. Simulations were executed on an Intel Pentium IV with a 2.6 GHz processor, and 1 GB of main memory, running the Windows XP operating system. The performance results obtained from the simulator are consistent with those of the replication service prototype.

In the implementation intended for the Grid5000 platform, each peer manages multiple tasks in parallel (e.g. routing DHT messages, executing a DSR step, etc.) by using multithreading and other associated mechanisms (e.g. semaphores); in addition, peers communicate with each other by means of sockets and UDP depending on the message type. To have a topology close to real P2P overlay networks in this Grid platform, we determine the peers’ neighbors and we allow that every peer communicate only with its neighbors in the overlay network. Although the Grid5000 provides fast and reliable communication, which usually is not the case for P2P systems, it allows to validate the accuracy of APPA distributed algorithms and to evaluate the scalability of APPA services. We have deployed APPA over this platform because it was the largest network available to perform our experiments in a controllable manner. On the other hand, the implementation of the simulator conforms to the SimJava model with respect to parallel processing and peers communication. It is important to note that, in our simulator, only the P2P network topology and peer communications are simulated; full-fledged APPA services are deployed on top of the simulated network.
ANNEX B: PROOFS
This annex contains the proofs that P2P-reconciler assures eventual consistency among replicas and works correctly in the presence of failures. The proofs for P2P-reconciler-TA are identical to the corresponding proofs of the P2P-reconciler.

EVENTUAL CONSISTENCY
We first prove that P2P-reconciler assures eventual consistency among replicas. This proof assumes that the reconciliation objects stored in DHT are available according to the high availability property of the APPA’s PDM service. In addition, we assume that P2P-reconciler is used in the context of a virtual community. Members of a virtual community have common interests and actively participate on collaborative applications. However, they can leave the community at any time thereby ceasing forever their participation. Thus, the active nodes involved in a collaborative application may change with time.

Definition B.1 (active node) A node is active with respect to a collaborative application if it is connected to the application or “temporarily” disconnected. A temporary disconnection can be caused by a failure or a transient pause on the collaboration, and therefore it is followed by at least one more reconnection.

Lemma B.1 All active nodes apply reconciled actions to the local replicas in the same order.
Proof We first show that reconciled actions coming from different executions of the P2P-reconciler protocol are ordered.
- Each execution of the P2P-reconciler produces a schedule. Since a schedule is an ordered list of actions that do not violate constraints, actions of the same schedule are ordered.
- Assume now that \( S_1 \rightarrow S_2 \rightarrow \ldots \rightarrow S_l \) is a sequence of schedules produced by the P2P-reconciler protocol respectively at times \( t_1, t_2, \ldots, t_l \). Since it is disallowed to launch parallel executions of P2P-reconciler, \( t_1 < t_2 < \ldots < t_l \), and then we use the execution sequence to order schedules. This ordering is stored in the schedule history reconciliation object in the form of an ordered list of schedule identifiers (i.e. \( H = \{ S_1^{id}, S_2^{id}, \ldots, S_l^{id} \} \)). If schedules are ordered and reconciled actions inside every schedule are also ordered, then all reconciled actions produced by distinct executions of the P2P-reconciler are ordered.

Since all active nodes apply reconciled actions to their local replicas according to the order established in the schedule history \( H \), all active nodes apply reconciled actions in the same order \( \square \).

Lemma B.2 All active nodes eventually apply all reconciled actions to their local replicas.
Proof We have to show that if all active nodes stop the production of update actions so that at time \( t_i \) the P2P-reconciler concludes its last reconciliation (i.e. at \( t_i \), all actions are reconciled), then there is a time \( t_j, t_j > t_i \), at which all active nodes have applied all schedules produced by the P2P-reconciler protocol. Let \( H \) be the schedule history (noted \( H = \{ S_1^{id}, S_2^{id}, \ldots, S_l^{id} \} \), \( n \) be an active node, and \( S_k^{id} \) be the identifier of the last schedule locally applied by \( n \) (\( n \) knows \( S_l^{id} \)). P2P-reconciler works as follows. Whenever \( n \) connects, it locally applies all schedules that succeed \( S_l^{id} \) in the \( H \)’s ordered list in order to refresh its local replicas with actions that were reconciled while \( n \) was disconnected. In addition, \( n \) repeats this refreshing operation whenever \( n \) disconnects in order to apply actions that were reconciled while it was connected, if any exists. Since \( n \) is an active node, it is either connected or temporarily disconnected (i.e. it will reconnect at least one more time) at time \( t_i \). Thus, if \( n \) is connected at time \( t_i \), \( n \) will apply all schedules produced by the P2P-reconciler when it disconnects at time \( t_j (t_j > t_i) \). However, if \( n \) is disconnected at time \( t_i \), \( n \) will apply all schedules when it reconnects at time \( t_i \) (\( t_i > t_j \)). Consider now that the set \( TFS \) (Times at which Final States were achieved) holds all times \( t_i \) and \( t_j \) associated with all active nodes. Since no more update actions are produced after \( t_i \), the time \( t_i \) at which all active nodes will have applied all schedules produced by the P2P-reconciler protocol is the maximal value belonging to \( TFS \). \( \square \)
Theorem B.1 The P2P-reconciler protocol assures eventual consistency among replicas that are stored in active nodes of a collaborative application.

Proof In this proof we assume that all replicas $R_1, R_2, \ldots, R_i$ of the object $R$ have the same initial state. Thus, we have to show that the same set of reconciled actions is applied to all such replicas in the same order. If $R_1, R_2, \ldots, R_i$ are held by active nodes of a collaborative application, all reconciled actions are eventually applied to these replicas (Lemma B.2) in the same order (Lemma B.1).

CORRECTNESS

We prove in this section that P2P-reconciler is correct as it assures eventual consistency among replicas even in the presence of failures. This proof assumes that the reconciliation objects stored in DHT are available according to the high availability property of the APPA’s PDM service. It also assumes synchronous network communication for supporting the subset of messages that the P2P-reconciler protocol cannot lose. We use $n_{\text{start}}$ to denote the node that starts the reconciliation.

Lemma B.3 The P2P-reconciler protocol is resilient to failure on the $n_{\text{start}}$ node.

Proof The $n_{\text{start}}$ node is responsible for locking the schedule history, notifying the start of reconciliation to provider nodes, and requesting the cost provider for allocating reconciler nodes. Thus, if $n_{\text{start}}$ fails while launching the reconciliation, the following problems could happen: (1) the schedule history could remain forever locked; and (2) the provider nodes could wait forever for reconciler requests. We have to show that the P2P-reconciler protocol avoids such problems. In our solution, provider nodes are able to estimate the time required to perform the reconciliation. As a result, if a provider node $n$ realizes that it is inactive for a long time wrt. the estimated reconciliation time, $n$ infers that the reconciliation has crashed and initiates a recovery procedure, which first notifies the abnormal end of reconciliation to other provider nodes, and then requests that the schedule history provider unlocks the schedule history. Notice that any provider node is able to detect the reconciliation crash and perform the recovery procedure. For this reason, there is no problem if $n$ fails while recovering. In this case, another provider node will detect the crash later on and repeat the recovery procedure; duplicated notifications of crash and duplicated requests for unlock the schedule history are discarded. Since provider nodes no longer wait for requests and the schedule history is unlocked, the P2P-reconciler protocol is resilient to failure on the $n_{\text{start}}$ node.

Lemma B.4 The P2P-reconciler protocol is resilient to failure on the cost provider node.

Proof The cost provider node is responsible for selecting and notifying reconciler nodes. Thus, if cost provider fails, the following problems could happen: (1) none reconciler node is allocated; or (2) only a subset of selected nodes is notified of allocation. We have to show that reconciliation can be normally restarted after the cost provider failure. In practice, problem 1 is equivalent to $n_{\text{start}}$ failure, i.e. if none reconciler is allocated, the schedule history could remain forever locked and the provider nodes could wait forever for reconciler requests. We proved in Lemma B.3 that the P2P-reconciler protocol works properly in this case. On the other hand, if some reconcilers are already notified when the cost provider fails, two scenarios are possible: (a) the reconciliation succeeds even with the reduced number of allocated reconcilers; or (b) the reconciliation crashes at time $t_c$ due to the lack of reconcilers. In the latter case, it is likely that the reconciliation objects have been updated. Thus, the recovery procedure works as follows. The provider node $n$ that detects the reconciliation crash notifies this fact to other provider nodes, which, in turn, undo updates performed on reconciliation objects up to time $t_c$, and then quit the reconciliation. In addition, $n$ requests that the schedule history provider unlocks the schedule history. As explained in the proof of Lemma B.3, there is no problem if $n$ fails while performing the recovery procedure. Since provider nodes undo updates on reconciliation objects before quitting the reconciliation and the schedule history is unlocked, the reconciliation can be normally restarted and, as a result, the P2P-reconciler protocol is resilient to failure on the cost provider node.
Lemma B.5 A reconciliation step “i” terminates properly if at least one reconciler node allocated to step “i” works properly until the end of “i”.

Proof P2P-reconciler protocol is composed of one allocation step (step 1) followed by five reconciliation steps (steps from 2 to 6). We have to show that if at least one reconciler node works properly until the end of each step from 2 to 6, the reconciliation as a whole succeeds. We first show that one reconciler is enough to successfully terminate step 2, and then we generalize the main principles for other steps.

- In step 2, reconciler nodes take actions from the action log providers and store back groups of potentially conflicting actions. On the one side, reconcilers remain requesting actions and storing back groups until the action log provider indicates that there are no more actions to group. On the other side, the action log provider supplies actions to reconcilers and waits for the corresponding acknowledgements that indicate the successful processing of such actions. These acknowledgements are carried by requests for storing groups. After a given delay, actions that were not acknowledged are redistributed to reconcilers that have requested more actions. This redistribution repeats until all actions have been acknowledged. In addition, the action log provider discards duplicated requests for storing groups, if any exists. Suppose now that only a reconciler \( n \) works properly during step 2. In this case, \( n \) repeatedly requests actions and stores back the associated groups until the action log provider indicates the end of actions and, as a result, step 2 terminates successfully.

- The general principles applied on step 2 (\( i = 2 \)) are described as follows. Let \( \text{maxRec} \) be the maximal number of reconcilers per step. Step \( i \) is divided into \( k \) cycles, where \( 1 \leq k \leq \text{maxRec} \). At each cycle, all reconcilers that still work properly request inputs from provider nodes and give back the associated acknowledgements in order to indicate the successful processing of inputs. This goal is achieved with no additional network traffic as the acknowledgments are inserted in the regular messages of the P2P-reconciler protocol. Provider nodes on the other hand discard duplicated update requests, if any exists, and control the end of step cycles. Because of the number of inputs to be distributed is equal to \( \text{maxRec} \), if all reconcilers work properly in step \( i \), \( i \) only needs one cycle to successfully terminate. However, if only one reconciler works properly during step \( i \), \( \text{maxRec} \) cycles need to be performed until the end of step \( i \).

Since all steps from 2 to 6 apply the general principles explained above, every reconciliation step \( i \) terminates properly if at least one reconciler node works properly until the end of \( i \).

Lemma B.6 The P2P-reconciler protocol is resilient to failures on reconciler nodes.

Proof We have to show that after a reconciler failure either the reconciliation terminates correctly or it can be normally restarted later on. Let \( n \) be the faulty reconciler node. We directly infer from Lemma B.5 that if \( n \) is not the last alive reconciler of a reconciliation step then the reconciliation terminates correctly. Otherwise, the reconciliation crashes due to the lack of reconcilers for concluding the step to which \( n \) is allocated. We proved in Lemma B.4 that in this case the reconciliation can be normally restarted. Since after a reconciler failure either the reconciliation terminates correctly or it can be normally restarted, the P2P-reconciler protocol is resilient to failures on reconciler nodes.

Theorem B.2 The P2P-reconciler protocol is correct even in the presence of failures.

Proof The execution of P2P-reconciler protocol involves four types of nodes: the node that starts the reconciliation (\( n_{\text{start}} \)), the cost provider, the reconciler nodes, and other nodes that hold reconciliation objects in DHT. Since we assume available reconciliation objects, we do not discuss failures at nodes that hold these objects. Thus, we have only to show that the P2P-reconciler protocol is resilient to failures on \( n_{\text{start}} \), cost provider, and reconciler nodes. This is proved respectively in Lemmas B.3, B.4, and B.6.

ABSTRACT
Distributed Hash Tables (DHTs) provide a scalable solution for data sharing in P2P systems. To ensure high data availability, DHTs typically rely on data replication, yet without data currency guarantees. Supporting data currency in replicated DHTs is difficult as it requires the ability to return a current replica despite peers leaving the network or concurrent updates. In this paper, we give a complete solution to this problem. We propose an Update Management Service (UMS) to deal with data availability and efficient retrieval of current replicas based on timestamping. For generating timestamps, we propose a Key-based Timestamping Service (KTS) which performs distributed timestamp generation using local counters. Through probabilistic analysis, we compute the expected number of replicas which UMS must retrieve for finding a current replica. Except for the cases where the availability of current replicas is very low, the expected number of retrieved replicas is typically small, e.g. if at least 35% of available replicas are current then the expected number of retrieved replicas is less than 3. We validated our solution through implementation and experimentation over a 64-node cluster and evaluated its scalability through simulation up to 10,000 peers using SimJava. The results show the effectiveness of our solution. They also show that our algorithm used in UMS achieves major performance gains, in terms of response time and communication cost, compared with a baseline algorithm.

1. INTRODUCTION
Peer-to-peer (P2P) systems adopt a completely decentralized approach to data sharing and thus can scale to very large amounts of data and users. Popular examples of P2P systems such as Gnutella [9] and KaZaA [12] have millions of users sharing petabytes of data over the Internet. Initial research on P2P systems has focused on improving the performance of query routing in unstructured systems, such as Gnutella and KaZaA, which rely on flooding. This work led to structured solutions based on distributed hash tables (DHT), e.g. CAN [19], Chord [29], and Pastry [23]. While there are significant implementation differences between DHTs, they all map a given key k onto a peer p using a hash function and can lookup p efficiently, usually in O(\log n) routing hops where n is the number of peers [5]. DHTs typically provide two basic operations [5]: put(k, data) stores a key k and its associated data in the DHT using some hash function; get(k) retrieves the data associated with k in the DHT.

One of the main characteristics of P2P systems is the dynamic behavior of peers which can join and leave the system frequently, at anytime. When a peer gets offline, its data becomes unavailable. To improve data availability, most DHTs rely on data replication by storing (k, data) pairs at several peers, e.g. using several hash functions [19]. If one peer is unavailable, its data can still be retrieved from the other peers that hold a replica. However, the mutual consistency of the replicas after updates can be compromised as a result of peers leaving the network or concurrent updates. Let us illustrate the problem with a simple update scenario in a typical DHT. Let us assume that the operation put(k, d0) (issued by some peer) maps onto peers p1 and p2, which both get to store the data d0. Now consider an update (from the same or another peer) with the operation put(k, d1) which also maps onto peers p1 and p2. Assuming that p2 cannot be reached, e.g. because it has left the network, then only p1 gets updated to store d1. When p2 rejoins the network later on, the replicas are not consistent: p1 holds the current state of the data associated with k while p2 holds a stale state. Concurrent updates also cause inconsistency. Consider now two updates put(k, d1) and put(k, d3) (issued by two different peers) which are sent to p1 and p2 in reverse order, so that p2’s last state is d3 while p1’s last state is d1. Thus, a subsequent get(k) operation will return either stale or current data depending on which peer is looked up, and there is no way to tell whether it is current or not. For some applications (e.g. agenda management, bulletin boards, cooperative auction management, reservation management, etc.) which could take advantage of a DHT, the ability to get the current data is very important.

Many solutions have been proposed in the context of distributed database systems for managing replica consistency [17] but the
high numbers and dynamic behavior of peers make them no longer applicable to P2P [6]. Supporting data currency in replicated DHTs requires the ability to return a current replica despite peers leaving the network or concurrent updates. The problem is partially addressed in [13] using data versioning. Each replica has a version number which is increased after each update. To return a current replica, all replicas need to be retrieved in order to select the latest version. However, because of concurrent updates, it may happen that two different replicas have the same version number thus making it impossible to decide which one is the current replica.

In this paper, we give a complete solution to data availability and data currency in replicated DHTs. Our main contributions are the following:

• We propose a service called Update Management Service (UMS) which deals with improving data availability and efficient retrieval of current replicas based on timestamping. After retrieving a replica, UMS detects whether it is current or not, i.e. without having to compare with the other replicas, and returns it as output. Thus, in contrast to the solution in [13], UMS does not need to retrieve all replicas to find a current one. In addition, concurrent updates raise no problem for UMS.

• We give a probabilistic analysis of UMS’s communication cost. We compute the expected number of replicas which UMS must retrieve for finding a current replica. We prove that it is less than the inverse of the probability of currency and availability, i.e. the probability that a replica is current and available. Thus, except for the cases where the availability of current replicas is very low, the expected number of replicas which UMS must retrieve is typically small.

• We propose a new Key-based Timestamping Service (KTS) which generates monotonically increasing timestamps, in a distributed fashion using local counters. KTS does distributed timestamp generation in a way that is similar to data storage in the DHT, i.e. using peers dynamically chosen by hash functions. To maintain timestamp monotonicity, we propose algorithms which take into account the cases where peers leave the system either normally or not (e.g. because they fail). To the best of our knowledge, this is the first paper that introduces the concept of key-based timestamping, and proposes efficient techniques for realizing this concept in DHTs. Furthermore, KTS is useful to solve other DHT problems which need a total order on operations performed on each data, e.g. read and write operations which are performed by concurrent transactions.

• We provide a comprehensive performance evaluation based on the implementation of UMS and KTS over a 64-node cluster. We also evaluated the scalability of our solution through implementation and simulation. In Section 6, we discuss related work. Section 7 concludes.

2. DHT MODEL AND PROBLEM STATEMENT

In this section, we first present a model of DHTs which is needed for describing our solution and proving its properties. Then, we precisely state the problem.

2.1 DHT Model

A DHT maps a key k to a peer p using a hash function h. We call p the responsible for k wrt h. A peer may be responsible for k wrt a hash function h₁ but not responsible for k wrt another hash function h₂. The responsible for k wrt h may be different at different times, i.e. because of peers’ joins and leaves. We can model the mapping mechanism of DHT as a function that determines at anytime the peer that is responsible for k wrt h; we call this function DHT’s mapping function.

Definition 1: DHT’s mapping function. Let K be the set of all keys accepted by the DHT, P the set of peers, H the set of all pairwise independent hash functions which can be used by the DHT for mapping, and T the set of all numbers accepted as time. We define the DHT’s mapping function as m: K×H×T → P such that m(k,h,t) determines the peer p ∈ P which is responsible for k ∈ K wrt h ∈ H at time t ∈ T.

Let us make precise the terminology involving peers’ responsibility for a key. Let k ∈ K, h ∈ H and p ∈ P, and let [t₀, t₁) be a time interval such that t₁ ≥ t₀. We say that p is continuously responsible for k wrt h in [t₀, t₁) if it is responsible for k wrt h at any time in [t₀, t₁). In other words, (∀t ∈ T, t₀ ≤ t < t₁) ⇒ (p = m(k, h, t)). If p obtains and loses the responsibility for k wrt h respectively at t₀ and t₁, and is continuously responsible for k wrt h in [t₀, t₁), then we say that [t₀, t₁) is a p’s period of responsibility for k wrt h. The peer that is responsible for k wrt h at current time is denoted by rsp(k, h). We also denote by prsp(k, h) the peer that was responsible for k wrt h just before rsp(k, h). The peer that will become responsible for k wrt h just after rsp(k, h) is denoted by nrsp(k, h).

Example 1. Figure 1 shows the peers responsible for k ∈ K wrt h ∈ H since t₀. The peer that is currently responsible for k wrt h is p₁; thus p₁ = rsp(k, h) and p₁ = prsp(k, h). In the time interval [t₁, t₂), p₂ is continuously responsible for k wrt h. It has obtained and lost its responsibility respectively at t₁ and t₂, thus [t₁, t₂) is p₂’s period of responsibility for k wrt h. Also [t₀, t₁) and [t₂, t₃) are respectively p₁’s and p₃’s periods of responsibility for k wrt h.

Figure 1. Example of peers’ responsibilities

In the DHT, there is a lookup service that can locate rsp(k, h) efficiently. The lookup service can return the address of rsp(k, h) usually in O(\log |P|) routing hops, where |P| is the number of peers in the system.
2.2 Problem Statement
To improve data availability we replicate the pairs \((k, data)\) at several peers using several hash functions. We assume that there is an operation that stores a pair \((k, data)\) at \(rs(k,h)\) which we denote by \(put(k, data)\). This operation can be issued concurrently by several peers. There is another operation, denoted by \(get(k)\), that retrieves the data associated with \(k\) which is stored at \(rs(k,h)\).

Over time, some of the replicas stored with \(k\) at some peers may get stale. Our objective is to provide a mechanism which returns efficiently a current replica in response to a query requesting the data associated with a key.

Formally, the problem can be defined as follows. Given a key \(k \in K\), let \(R_k\) be the set of replicas such that for each \(r \in R_k\), the pair \((k, r)\) is stored at one of the peers of the DHT. Our goal is to return efficiently an \(r \in R_k\) which is current, i.e. reflects the latest update.

3. UPDATE MANAGEMENT SERVICE
To deal with data currency in DHTs, we propose an Update Management Service (UMS) which provides high data availability through replication and efficient retrieval of current replicas. UMS only requires the DHT’s lookup service with \(put\) and \(get\) operations. To return current replicas, it uses timestamps attached to the pairs \((k, data)\). In this section, we give an overview of our timestamping solution and present in more details UMS’ update operations. We also analyze UMS’s communication cost.

3.1 Timestamping
To provide high data availability, we replicate the data in the DHT using a set of pairwise independent hash functions \(H_i \subset H\) which we call replication hash functions. To be able to retrieve a current replica we “stamp” each pair \((k, data)\) with a logical timestamp, and for each \(h \in H_i\) we replicate the pair \((k, newData)\) at \(rs(k,h)\) where \(newData=[data, timestamp]\), i.e. \(newData\) is a data composed of the initial data and the timestamp. Upon a request for the data associated with a key, we can thus return one of the replicas which are stamped with the latest timestamp. The number of replication hash functions, i.e. \(|H_i|\), can be different for different DHTs. For instance, if in a DHT the availability of peers is low, for increasing data availability a high value of \(|H_i|\) (e.g. 30) is used. Constructing \(H_i\) which is a set of pairwise independent hash functions, can be done easily, e.g. by using the methods presented in [14].

To generate timestamps, we propose a distributed service called Key-based Timestamping Service (KTS). The main operation of KTS is \(gen\_ts(k)\) which given a key \(k\) generates a real number as a timestamp for \(k\). The timestamps generated by KTS have the monotonicity property, i.e. two timestamps generated for the same key are monotonically increasing. This property permits us to order the timestamps generated for the same key according to the time at which they have been generated.

Definition 2: Timestamp monotonicity. For any two timestamps \(ts_1\) and \(ts_2\) generated for a key \(k\) respectively at times \(t_1\) and \(t_2\), if \(t_1 < t_2\) then we have \(ts_1 < ts_2\).

At anytime, KTS generates at most one timestamp for a key (see Section 4 for the details). Thus, regarding to the monotonicity property, there is a total order on the set of timestamps generated for the same key. However, there is no total order on the timestamps generated for different keys.

KTS has another operation denoted by \(last\_ts(k)\) which given a key \(k\) returns the last timestamp generated for \(k\) by KTS.

3.2 Update Operations
To describe UMS, we use the \(KTS.gen\_ts\) and \(KTS.last\_ts\) operations discussed above. The implementation of these operations is detailed in Section 4. UMS provides \(insert\) and \(retrieve\) operations (see Figure 2).

\begin{verbatim}
insert(k, data)
begin
    ts := KTS.gen_ts (k);
    for each h∈H_i do
        newData := {data, ts};
        DHT.put(h(k, newData));
    end;
end;

retrieve(k)
begin
    ts1 := KTS.last_ts(k);
    dataMr := null;
    tSmr := -∞;
    for each h∈H_i do begin
        newData := DHT.get(h(k));
        data := newData.data;
        ts := newData.ts;
        if (ts = ts1) then begin
            return data; // one current
        end;
    end;
end;

Figure 2. UMS update operations
\end{verbatim}

for the same key. However, there is no total order on the timestamps generated for different keys.

\begin{verbatim}
KTS has another operation denoted by \(last\_ts\) which given a key \(k\) returns the last timestamp generated for \(k\) by KTS.

3.2 Update Operations
To describe UMS, we use the \(KTS.gen\_ts\) and \(KTS.last\_ts\) operations discussed above. The implementation of these operations is detailed in Section 4. UMS provides \(insert\) and \(retrieve\) operations (see Figure 2).

Insert(k, data): inserts a pair \((k, data)\) in the DHT as follows. First, it uses KTS to generate a timestamp for \(k\), e.g. \(ts\). Then, for each \(h \in H\), it sends the pair \((k,\{data, ts\})\) to the peer that is \(rs(k,h)\). When a peer \(p\) receives the pair \((k,\{data, ts\})\), it compares \(ts\) with the timestamp, say \(ts_0\), of its data (if any) associated with \(k\). If \(ts > ts_0\), \(p\) overwrites its data and timestamp with the new ones. Recall that, at anytime, \(KTS.gen\_ts(k)\) generates at most one timestamp for \(k\), and different timestamps for \(k\) have the monotonicity property. Thus, in the case of concurrent calls to \(insert(k, data)\), i.e. from different peers, only the one that obtains the latest timestamp will succeed to store its data in the DHT.

Retrieve(k): retrieves the most recent replica associated with \(k\) in the DHT as follows. First, it uses KTS to determine the latest timestamp generated for \(k\), e.g. \(ts\). Then, for each hash function \(h \in H\), it uses the DHT operation \(get(h)\) to retrieve the pair \([data, timestamp]\) stored along with \(k\) at \(rs(k,h)\). If \(timestamp\) is equal to \(ts\), then the data is a current replica which is returned as output.
\end{verbatim}
and the operation ends. Otherwise the retrieval process continues while saving in data px, the most recent replica. If no replica with a timestamp equal to ts is found (i.e. no current replica is found) then the operation returns the most recent replica which is available, i.e. data px.

3.3 Cost Analysis
In this section, we give a probabilistic analysis of the communication cost of UMS in terms of number of messages to retrieve a data item. For a non replicated DHT, this cost, which we denote by c_retrieve, is O(log n) messages where n is the number of peers. The communication cost of retrieving a current replica by UMS is c_retrieve = c_retrieve + n_retrieve * c_retrieve where c_retrieve is the cost of returning the last generated timestamp by KTS and n_retrieve is the number of replicas that UMS retrieves, i.e. the number of times that the operation getts(k) is called. As we will see in the next section, c_retrieve is usually equal to c_retrieve, i.e. the cost of contacting the responsible of a key and getting the last timestamp from it. Thus, we have c_retrieve = (1 + n_retrieve) * c_retrieve.

The number of replicas which UMS retrieves, i.e. n_retrieve, depends on the probability of currency and availability of replicas. The higher this probability, the lower n_retrieve is. Let H_r be the set of replication hash functions, t be the retrieval time, and p_t be the probability that, at time t, a current replica is available at a peer that is responsible for k wrt some h ∈ H_r. In other words, p_t is the ratio of current replicas, which are available at t over the peers responsible for k wrt replication hash functions, to the total number of replicas, i.e. |H_r|/t. We call p_t the probability of currency and availability at retrieval time. We give a formula for computing the expected value of the number of replicas, which UMS retrieves, in terms of p_t and |H_r|/t. Let X be a random variable which represents the number of replicas that UMS retrieves. We have Prob(X = i) = p_t * (1 - p_t) ^ (i - 1), i.e. the probability of having X = i is equal to the probability that i - 1 first retrieved replicas are not current and the ith replica is current. The expected value of X is computed as follows:

\[ E(X) = \sum_{i=0}^{\infty} i \cdot \Pr(X = i) \]

Equation 1 expresses the expected value of the number of retrieved replicas in terms of p_t and |H_r|/t. Thus, we have the following upper bound for E(X) which is solely in terms of p_t:

\[ E(X) < p_t \cdot \sum_{i=0}^{\infty} i \cdot (1 - p_t) ^ {i-1} \]

From the theory of series [2], we use the following equation for 0 ≤ z < 1:

\[ \sum_{i=0}^{\infty} i \cdot z ^ {i-1} = \frac{1}{(1-z)^2} \]

Since 0 ≤ (1 - p_t) < 1, we have:

\[ \sum_{i=0}^{\infty} i \cdot (1 - p_t) ^ {i-1} = \frac{1}{(1-(1-p_t))^2} \]

Using Equations 3 and 2, we obtain:

\[ E(X) < \frac{1}{p_t} \]

Theorem 1: The expected value of the number of replicas which UMS retrieves is less than the inverse of the probability of currency and availability at retrieval time.

Proof: Implied by the above discussion.

Example. Assume that at retrieval time 35% of replicas are current and available, i.e. p_t = 0.35. Then the expected value of the number of replicas which UMS retrieves is less than 3.

Intuitively, the number of retrieved replicas cannot be more than |H_r|. Thus, for E(X) we have:

\[ E(X) \leq \min\left(\frac{1}{p_t} \cdot |H_r|, 1\right) \]

4. KEY-BASED TIMESTAMP SERVICE
The main operation of KTS is gen ts which generates monotonically increasing timestamps for keys. A centralized solution for generating timestamps is obviously not possible in a P2P system since the central peer would be a bottleneck and single point of failure. Distributed solutions using synchronized clocks no longer apply in a P2P system. One popular method for distributed clock synchronization is Network Time Protocol (NTP) which was originally intended to synchronize computers linked via Internet networks [16]. NTP and its extensions (e.g. [8] and [18]) guarantee good synchronization precision only if computers are linked together long enough and communicate frequently [18]. However, in a P2P system in which peers can leave the system at any time, these solutions cannot provide good synchronization precision.

In this section, we propose a distributed technique for generating timestamps in DHTs. First, we present a technique based on local counters for generating the timestamps. Then we present a direct algorithm and an indirect algorithm for initializing the counters, which is very important for guaranteeing the monotonicity of timestamps. We also apply the direct algorithm to CAN and Chord. Finally, we discuss a method for maintaining the validity of counters.

4.1 Timestamp Generation
Our idea for timestamping in DHTs is like the idea of data storage in these networks which is based on having a peer responsible for storing each data and determining the peer dynamically using a hash function. In KTS, for each key we have a peer responsible for timestamping which is chosen dynamically using a hash function. Below, we discuss the details of timestamp responsibility and timestamp generation.

4.1.1 Timestamping Responsibility
Timestamp generation is performed by KTS as follows. Let k ∈ K be a key, the responsible of timestamping for k is the peer that is responsible for k wrt h k, i.e. rsp(k, h k), where h k is a hash function accepted by the DHT, i.e. h k ∈ H. Each peer q that needs a timestamp for k, called timestamp requester, uses the DHT’s lookup service to obtain the address of rsp(k, h k) to which it sends a timestamp request (TSR). When rsp(k, h k) receives the request of q, generates a timestamp for k and returns it to q. Figure 3 illustrates the generation of a timestamp for k initiated by peer q.
If the peer that is \( rsvp(k, h_o) \) leaves the system or fails, the DHT detects the absence of that peer, e.g. by frequently sending “ping” messages from each peer to its neighbors [19], and another peer becomes responsible for \( k \) wrt \( h_o \). Therefore, if the responsible of timestamping for \( k \) leaves the system or fails, another peer automatically becomes responsible of timestamping for \( k \), i.e. the peer that becomes responsible for \( k \) wrt \( h_o \). Thus, the dynamic behavior of peers causes no problem for timestamping responsibility.

4.1.2 Guaranteeing Monotonicity

Let us now discuss what a responsible of timestamping should do to maintain the monotonicity property. Let \( k \) be a key, \( p \) the peer that is responsible of timestamping for \( k \), and \( ts_k \) a timestamp for \( k \) which is generated by \( p \). To provide the monotonicity property, we must guarantee two constraints: (1) \( ts_k \) is greater than all timestamps for \( k \) which have been previously generated by \( p \) itself; (2) \( ts_k \) is greater than any timestamp for \( k \) generated by any other peer that was responsible for timestamping for \( k \) in the past.

To enforce the first constraint, for generating timestamps for each key \( k \), we use a local counter of \( k \) at \( p \) which we denote as \( c_{p,k} \). When \( p \) receives a timestamp request for \( k \), it increments the value of \( c_{p,k} \) by one and returns it as the timestamp for \( k \) to the timestamp requester.

To enforce the second constraint, \( p \) should initialize \( c_{p,k} \) so that it is greater than or equal to any timestamp for \( k \) previously generated by other peers that were responsible of timestamping for \( k \) in the past. For this, \( p \) initializes \( c_{p,k} \) to the last value of \( c_{p,k} \) where \( q \) is the last peer that has generated a timestamp for \( k \). In Section 4.2, we discuss how \( p \) can acquire \( c_{p,k} \). The following lemma shows that the initialization of \( c_{p,k} \) as above enforces the second constraint.

**Lemma 1:** If each peer \( p \), during each of its periods of responsibility for \( k \) wrt \( h_o \), initializes \( c_{p,k} \) before generating the first timestamp for \( k \), then each generated timestamp for \( k \) is greater than any previously generated one.

**Proof:** Follows from the fact that initializing \( c_{p,k} \) makes it equal to the last timestamp generated for \( k \), and the fact that timestamp generation is done by increasing the value of \( c_{p,k} \) by one and returning its value as output. □

After \( c_{p,k} \) has been initialized, it is a valid counter, i.e. \( p \) can use it for generating timestamps for \( k \). If \( p \) loses the responsibility for \( k \) wrt \( h_p \), e.g. because of leaving the system, then \( c_{p,k} \) becomes invalid. The peer \( p \) keeps its valid counters in a Valid Counters Set which we denote by \( VCSp \). In other words, for each \( k \in K \), if \( c_{p,k} \) is valid then \( c_{p,k} \) is in \( VCSp \). Each peer \( p \in P \) has its own \( VCSp \) and respects the following rules for it:

1. When \( p \) joins the P2P system, it sets \( VCSp = \emptyset \).
2. \( \forall k \in K \), when \( p \) initializes \( c_{p,k} \), it adds \( c_{p,k} \) to \( VCSp \).
3. \( \forall k \in K \), when \( p \) loses the responsibility for \( k \) wrt \( h_o \), if \( c_{p,k} \) is in \( VCSp \), then \( p \) removes it from \( VCSp \).

When \( p \) receives a timestamp request for a key \( k \), it checks for the existence of \( c_{p,k} \) in \( VCSp \). If \( c_{p,k} \) is in \( VCSp \), then \( p \) generates the timestamp for \( k \) using \( c_{p,k} \). Otherwise \( p \) initializes \( c_{p,k} \), appends it to \( VCSp \) and then generates the timestamp using \( c_{p,k} \) (see Figure 4).

The data structure used for \( VCSp \) is such that given a key \( k \) seeking \( c_{p,k} \) in \( VCSp \) can be done rapidly, e.g. a binary search tree. Also, for minimizing the memory cost, when a counter gets out of \( VCSp \), \( p \) releases the memory occupied by the counter, i.e. only the counters involved in \( VCSp \) occupy a memory location. To prevent the problem of overflow, we use a large integer, e.g. 128 bits, for the value of \( c_{p,k} \).

The following theorem shows that using \( VCSp \) and respecting its rules guarantees the monotonicity property.

**Theorem 2:** If the peer \( p \), which is responsible for \( k \) wrt \( h_o \), for generating timestamps for \( k \) uses \( c_{p,k} \) that is in \( VCSp \), then each generated timestamp for \( k \) is greater than any previously generated one.

**Proof:** Let \( [t_0, t_1) \) be a \( p \)’s period of responsibility for \( k \) wrt \( h_o \) and let us assume that \( p \) generates a timestamp for \( k \) in \( [t_0, t_1) \). Rules 1 and 3 assure that at \( t_0 \), \( c_{p,k} \) is not in \( VCSp \). Thus, for generating the first timestamp for \( k \) in \( [t_0, t_1) \), \( p \) should initialize \( c_{p,k} \) and insert it into \( VCSp \) (Rule 2). Therefore, in each of its periods of responsibility for \( k \) wrt \( h_o \), \( p \) initializes \( c_{p,k} \) before generating the first timestamp for \( k \). Thus, each peer \( p \), during each of its periods of responsibility for \( k \) wrt \( h_o \), initializes \( c_{p,k} \) before generating the first timestamp for \( k \), so by Lemma 1 the proof is complete. □

The other KTS operation \( last_ts(k) \), which we used in Section 3, can be implemented like \( gen_ts(k) \) except that \( last_ts \) is simpler: it only returns the value of \( c_{p,k} \) and does not need to increase its value.
4.2 Counter Initialization

Initializing the counters is very important for maintaining the monotonicity property. Recall that for initializing $c_{p,k}$, the peer $p$, which is responsible of timestamping for $k$, assigns to $c_{q,k}$ the value of $c_{q,k}$ where $q$ is the last peer that has generated a timestamp for $k$. But, the question is how $p$ can acquire $c_{q,k}$. To answer this question, we propose two initialization algorithms: direct and indirect. The direct algorithm is based on transferring directly the counters from a responsible of timestamping to the next responsible. The indirect algorithm is based on retrieving the value of the last generated timestamp from the DHT.

4.2.1 Direct Algorithm for Initializing Counters

With the direct algorithm, the initialization is done by directly transferring the counters from a responsible of timestamping to the next one at the end of its responsibility. This algorithm is used in situations where the responsible of timestamping loses its responsibility in a normal way, i.e. it does not fail.

Let $q$ and $p$ be two peers, and $K'\subseteq K$ be the set of keys for which $q$ is the current responsible of timestamping and $p$ is the next responsible. The direct algorithm proceeds as follows. Once $q$ reaches the end of its responsibility for the keys in $K'$, e.g. before leaving the system, it sends to $p$ all its counters that have been initialized for the keys involved in $K'$. Let $C$ be an empty set, $q$ performs the following instructions at the end of its responsibility:

\[
\text{for each } c_{q,k} \in VCS_q \text{ do} \\
\quad \text{if } (keK') \text{ then} \\
\quad \quad C := C + \{c_{q,k}\}; \\
\quad \quad \text{Send } C \text{ to } p;
\]

At the beginning of its responsibility for the keys in $K'$, $p$ initializes its counters by performing the following instructions:

\[
\text{for each } c_{q,k} \in C \text{ do begin} \\
\quad \quad \text{new}(c_{p,k}); \\
\quad \quad c_{p,k}.value := c_{q,k}.value; \\
\quad \quad VCS_p := VCS_p + \{c_{p,k}\}; \\
\quad \quad \text{end;}
\]

4.2.1.1 Application to CAN and Chord

The direct algorithm initializes the counters very efficiently, in $O(1)$ messages, by sending the counters from the current responsible of timestamping to the next responsible at the end of its responsibility. But, how can the current responsible of timestamping find the address of the next responsible? The DHT’s lookup service does not help here because it can only lookup the current responsible for $k$, i.e. $rsp(k, h_q)$, and cannot return the address of the next responsible for $k$. To answer the question, we observe that, in DHTs, the next peer that obtains the responsibility for a key $k$ is typically a neighbor of the current responsible for $k$, so the current responsible of timestamping has the address of the next one. We now illustrate this observation with CAN and Chord, two popular DHTs.

Let us assume that peer $q$ is $rsp(k, h)$ and peer $p$ is $nrsp(k, h)$ where $k\in K$ and $h\in H$. In CAN and Chord, there are only two ways by which $p$ would obtain the responsibility for $k$ wrt $h$. First, $q$ leaves the P2P system or fails, so the responsibility of $k$ wrt $h$ is assigned to $p$. Second, $p$ joins the P2P system which assigns it the responsibility for $k$ wrt $h$, so $q$ loses the responsibility for $k$ wrt $h$ despite its presence in the P2P system. We show that in both cases, $nrsp(k, h)$ is one of the neighbors of $rsp(k, h)$. In other words, we show that both CAN and Chord have the important property that $nrsp(k, h)$ is one of the neighbors of $rsp(k, h)$ at the time when $rsp(k, h)$ loses the responsibility for $k$ wrt $h$.

CAN. We show this property by giving a brief explanation of CAN’s protocol for joining and leaving the system [19]. CAN maintains a virtual coordinate space partitioned among the peers. The partition which a peer owns is called its zone. According to CAN, a peer $p$ is responsible for $k$ wrt $h$ if and only if $h(k)$, which is a point in the space, is in $p$’s zone. When a new peer, say $p$, wants to join CAN, it chooses a point $X$ and sends a join request to the peer whose zone involves $X$. The current owner of the zone, say $q$, splits its zone in half and the new peer occupies one half, then $q$ becomes one of $p$’s neighbors. Thus, in the case of join, $nrsp(k, h)$ is one of the neighbors of $rsp(k, h)$. Also, when a peer $p$ leaves the system or fails, its zone will be occupied by one of its neighbors, i.e. the one that has the smallest zone. Thus, in the case of leave or fail, $nrsp(k, h)$ is one of the neighbors of $rsp(k, h)$, and that neighbor is known for $rsp(k, h)$.

Chord. In Chord [29], each peer has an $m$-bit identifier (ID). The peer IDs are ordered in a circle and the neighbors of a peer are the peers whose distance from $p$ clockwise in the circle is $2^i$ for $0 \leq i \leq m$. The responsible for $k$ wrt $h$ is the first peer whose ID is equal or follows $h(k)$. Consider a new joining peer $p$ with identifier $ID_p$. Suppose that the position of $p$ in the circle is just between two peers $q_1$ and $q_2$ with identifiers $ID_1$ and $ID_2$, respectively. Without loss of generality, we assume that $ID_1 < ID_2$. Thus, we have $ID_1 < ID_p < ID_2$. When $p$ joins Chord, it becomes responsible for $k$ wrt $h$ if and only if $ID_1 < h(k) \leq ID_2$. When $p$ joins Chord, it becomes responsible for $k$ wrt $h$ if and only if $ID_1 < h(k) \leq ID_p$. In other words, $p$ becomes responsible for a part of the keys for which $q_2$ was responsible. Since the distance clockwise from $p$ to $q_2$ is $2^j$, $q_2$ is a neighbor of $p$. Thus, in the case of join, $nrsp(k, h)$ is one of the neighbors of $rsp(k, h)$. When a peer $p$ leaves the system or fails, the next peer in the circle, say $q_2$, becomes responsible for its keys. Since the distance clockwise from $p$ to $q_2$ is $2^j$, $q_2$ is a neighbor of $p$.

Following the above discussion, when a peer $q$ loses the responsibility for $k$ wrt $h$ in Chord or CAN, one of its neighbors, say $p$, is the next responsible for all keys for which $q$ was responsible. Therefore, to apply the direct algorithm, it is sufficient that, before losing its responsibility, $q$ sends to $p$ its initialized counters, i.e. those involved in $VCS_p$.

4.2.2 Indirect Algorithm for Initializing Counters

With the direct algorithm, the initialization of counters can be done very efficiently. However, in some situations the direct algorithm cannot be used, e.g. when a responsible of timestamping fails. In those situations, we use the indirect algorithm. For initializing the counter of a key $k$, the indirect algorithm retrieves the most recent timestamp which is stored in the DHT along with the pairs $(k, data)$. As described in Section 3.2, peers store the timestamps, which are generated by KTS, along with their data in the DHT.

The indirect algorithm for initializing the counters proceeds as follows (see Figure 5). Let $k$ be a key, $p$ be the responsible of timestamping for $k$, and $H_p$ be the set of replication hash functions for $k$.
which are used for replicating the data in the DHT as described in Section 3.2. To initialize \( c_{p,k} \), for each \( h \in H_r \), \( p \) retrieves the replica (and its associated timestamp) which is stored at \( rsp(k,h) \).

Among the retrieved timestamps, \( p \) selects the most recent one, say \( t_{sm} \), and initializes \( c_{p,k} \) to \( t_{sm} + 1 \). If no replica and timestamp is stored in the DHT along with \( k \), then \( p \) initializes \( c_{p,k} \) to 0.

If \( p \) is at the beginning of its responsibility of timestamping for \( k \), before using the indirect algorithm, it waits a while so that the possible timestamps, which are generated by the previous responsible of timestamping, be committed in the DHT by the peers that have requested them.

Let \( c_{cp} \) be the number of messages which should be sent over the network for retrieving a data from the DHT, the indirect algorithm is executed in \( O(|H_r|/c_{cp}) \) messages.

Let us now compute the probability that the indirect algorithm retrieves successfully the latest version of the timestamp from the DHT. We denote this probability as \( p_c \). Let \( t \) be the time at which we execute the indirect algorithm, and \( p_t \) be the probability of currency and availability at \( t \) (see Section 3.3 for the definition of the probability of currency and availability). If at least one of the peers, which are responsible for \( k \) wrt replication hash functions, owns a current replica then the indirect algorithm works successfully. Thus, \( p_c \) can be computed as follows:

\[
p_c = 1 - (1 - p_t)\cdot p_c,
\]

Thus, we have:

\[
p_c = 1 - (1 - p_t)^{\frac{1}{|H_r|}}.
\]

In this equation, \( |H_r| \) is the number of replication hash functions. By increasing the number of replication hash functions, we can obtain a good probability of success for the indirect algorithm. For instance, if the probability of currency and availability is about 30%, then by using 13 replication hash functions, \( p_t \) is more than 99%.

By adjusting the number of replication hash functions, the probability of success of the indirect algorithm is high but not 100%. Thus, there may be some situations where it cannot retrieve the latest version of timestamp, in which case the counter of the key is not initialized correctly. To deal with these situations in a correct way, we propose the following strategies:

- **Recovery.** After restarting, the failed responsible of timestamping contacts the new responsible of timestamping, say \( p \), and sends it all its counters. Then, the new responsible of timestamping compares the received counters with those initialized by the indirect algorithm and corrects the counters which are initialized incorrectly (if any). In addition, if \( p \) has generated some timestamps with an incorrect counter, it retrieves the data which has been stored in the DHT with the latest value of the incorrect counter and reinserts the data into the DHT with the correct value of the counter.

- **Periodic inspection.** A responsible of timestamping which takes over a failed one, and which has not been contacted by it, periodically compares the value of its initialized counters with the timestamps which are stored in the DHT. If a counter is lower than the highest timestamp found, the responsible of timestamping corrects the counter. Furthermore, it reinserts the data which has been stored in the DHT with the latest value of the counter.

### 4.3 Validity of Counters

In Section 4.1, the third rule for managing VCSs states that if a peer \( p \) loses the responsibility for a key \( k \) wrt \( h_o \), then \( p \) should remove \( c_{p,k} \) from \( VCS_p \) (if it is there). We now discuss what \( p \) should do in order to respect the third rule for \( VCS_p \). If the reason for losing responsibility is that \( p \) has left the P2P system or failed, then there is nothing to do, since when \( p \) rejoins the P2P system, it sets \( VCS_p = \emptyset \). Therefore, we assume that \( p \) is present in the P2P system and loses the responsibility for \( k \) wrt \( h_o \) because some other peer joins the P2P system and becomes responsible for \( k \).

We can classify DHT protocols in two categories: **Responsibility Loss Aware (RLA)** and **Responsibility Loss Unaware (RLU)**. In an RLA DHT, a peer that loses responsibility for some key \( k \) wrt \( h \) and is still present in the P2P system detects its loss of responsibility. A DHT that is not RLA is RLU.

Most DHTs are RLA, because usually when a new peer \( p \) becomes \( rsp(k,h) \), it contacts \( prsp(k,h) \), say \( q \), and asks \( q \) to return the pairs \((k, data)\) which are stored at \( q \). Thus, \( q \) detects the loss of responsibility for \( k \). Furthermore, in most of DHTs, \( p \) is a new neighbor of \( q \) (see Section 4.2.1), so when \( p \) arrives \( q \) detects that it has lost the responsibility for some keys. For the DHTs that are RLA, the third rule of VCS can be enforced as follows. When a peer \( p \) detects that it has lost the responsibility for some keys wrt \( h_o \), it performs the following instructions:

For each \( c_{p,k} \in VCS_p \) do:

- If \( p \neq rsp(k,h_o) \) then
  - remove \( c_{p,k} \) from \( VCS_p \)

If the DHT is RLU, then Rule 3 can be violated. Let us illustrate with the following scenario. Let \( k \) be a key and \( p \) the peer that is \( rsp(k,h_o) \) which generates some timestamp for \( k \), i.e. \( c_{p,k} \) is in \( VCS_p \). Suppose another peer \( q \) joins the P2P system, becomes \( rsp(k,h_o) \) and generates some timestamps for \( k \). Then \( q \) leaves the DHT, and \( p \) becomes again \( rsp(k,h_o) \). In this case, if \( p \) generates a timestamp for \( k \) using \( c_{p,k} \in VCS_p \), the generated timestamp may be equal or less than the last generated timestamp for \( k \), thus violating the monotonicity property as a result of violating Rule 3.

To avoid such problems in a DHT that is RLU, we impose that \( rsp(k,h_o) \) assumes that after generating each timestamp for \( k \), it loses its responsibility for \( k \) wrt \( h_o \). Thus, after generating a timestamp for \( k \), it removes \( c_{p,k} \) from \( VCS_p \). Therefore, Rule 3 is enforced. However, by this strategy, for generating each timestamp for \( k \) we need to initialize \( c_{p,k} \) and this increases the cost of timestamp generation.
5. PERFORMANCE EVALUATION

In this section, we evaluate the performance of our Update Management Service (UMS) through implementation and simulation. The implementation over a 64-node cluster was useful to validate our algorithm and calibrate our simulator. The simulation allows us to study scale up to high numbers of peers (up to 10,000 peers).

The rest of this section is organized as follows. In Section 5.1, we describe our experimental and simulation setup, and the algorithms used for comparison. In Section 5.2, we first report experimental results using the implementation of UMS and KTS on a 64-node cluster, and then we present simulation results on performance by increasing the number of peers up to 10,000. In Sections 5.3, we evaluate the effect of the number of replicas, which we replicate for each data in the DHT, on performance. In Section 5.4, we study the effect of peers’ failures on performance. In Section 5.5, we study the effect of the frequency of updates on performance.

5.1 Experimental and Simulation Setup

Our implementation is based on Chord [29] which is a simple and efficient DHT. Chord’s lookup mechanism is provably robust in the face of frequent node fails, and it can answer queries even if the system is continuously changing. We implemented UMS and KTS as a service on top of Chord which we also implemented. In our implementation, the keys do not depend on the data values, so changing the value of a data does not change its key.

We tested our algorithms over a cluster of 64 nodes connected by a 1-Gbps network. Each node has 2 Intel Xeon 2.4 GHz processors, and runs the Linux operating system. We make each node act as a peer in the DHT.

To study the scalability of our algorithms far beyond 64 peers, we implemented a simulator using SimJava [27]. To simulate a peer, we use a SimJava entity that performs all tasks that must be done by a peer for executing the services KTS and UMS. We assign a delay to communication ports to simulate the delay for sending a message between two peers in a real P2P system. Overall, the simulation and experimental results were qualitatively similar. Thus, due to space limitations, for most of our tests, we only report simulation results.

The simulation parameters are shown in Table 1. We use parameter values which are typical of P2P systems [25]. The latency between any two peers is a normally distributed random number with a mean of 200 ms. The bandwidth between peers is also a random number with normal distribution with a mean of 56 (kbps). The simulator allows us to perform tests up to 10,000 peers, after which simulation data no longer fit in RAM and makes our tests difficult. Therefore, the number of peers is set to 10,000, unless otherwise specified.

In each experiment, peer departures are timed by a random Poisson process (as in [21]). The average rate, i.e. $\lambda$, for events of the Poisson process is $\lambda=1$/second. At each event, we select a peer to depart uniformly at random. Each time a peer goes away, another joins, thus keeping the total number of peers constant (as in [21]).

Peer departures are of two types: normal leave or fail. Let failure rate be a parameter that denotes the percentage of departures which are of fail type. When a departure event occurs, our simulator must decide on the type of this departure. For this, it generates a random number which is uniformly distributed in $[0,100]$; if the number is greater than failure rate then the peer departure is considered as a normal leave, else as a fail. In our tests, the default setting for fail rate is 5%.

In our experiments, each replicated data is updated by update operations which are timed by a random Poisson process. The default average rate for events of this Poisson process is $\lambda=1$/hour.

In our tests, unless otherwise specified, the number of replicas of each data is 10, i.e. $|H_i|=10$.

Although it cannot provide the same functionality as UMS, the closest prior work to UMS is the BRICKS project [13]. To assess the performance of UMS, we compare our algorithm with the BRICKS algorithm, which we denote as BRK. We tested two versions of UMS. The first one, denoted by UMS-Direct, is a version of UMS in which the KTS service uses the direct algorithm for initializing the counters. The second version, denoted by UMS-Indirect, uses a KTS service that initializes the counters by the indirect algorithm.

In our tests, we compare the performance of UMS-Direct, UMS-Indirect and BRK in terms of response time and communication cost. By response time, we mean the time to return a current replica in response to a query $Q$ requesting the data associated with a key. The communication cost is the total number of messages needed to return a current replica in response to $Q$. For each experiment, we perform 30 tests by issuing $Q$ at 30 different times which are uniformly distributed over the total experimental time, e.g. 3 hours, and we report the average of their results.

5.2 Scale up

In this section, we investigate the scalability of UMS. We use both our implementation and our simulator to study the response time and communication cost of UMS while varying the number of peers.

Using our implementation over the cluster, we ran experiments to study how response time increases with the addition of peers. Figure 6 shows the response time with the addition of peers until 64. The response time of all three algorithms grows
logarithmically with the number of peers. However, the response time of UMS-Direct and UMS-Indirect is significantly better than BRK. The reason is that, by using KTS and determining the last generated timestamp, UMS can distinguish the currency of replicas and return the first current replica which it finds while BRK needs to retrieve all available replicas, which hurts response time. The response time of UMS-Direct is better than UMS-Indirect because, for determining the last timestamp, UMS-Direct uses a version of KTS that initializes the counters by the direct algorithm which is more efficient than the indirect algorithm used by UMS-Indirect. Note that the reported results are the average of the results of several tests done at uniformly random times.

Using simulation, Figure 7 shows the response time of the three algorithms with the number of peers increasing up to 10000 and the other simulation parameters set as in Table 1. Overall, the experimental results correspond qualitatively with the simulation results. However, we observed that the response time gained from our experiments over the cluster is slightly better than that of simulation for the same number of peers, simply because of faster communication in the cluster.

We also tested the communication cost of UMS. Using the simulator, Figure 8 depicts the total number of messages while increasing the number of peers up to 10,000 with the other simulation parameters set as in Table 1. The communication cost increases logarithmically with the number of peers.

5.3 Effect of the Number of Replicas
In this section, we study the effect of the number of replicas, which we replicate for each data in the DHT, on the performance of UMS.

Using the simulator, Figures 9 and 10 show how respectively response time and communication cost evolve while increasing the number of replicas, with the other simulation parameters set as in Table 1. The number of replicas has a strong impact on the performance of BRK, but no impact on UMS-Direct. It has a little impact on the performance of UMS-Indirect because, in the cases where the counter of a key is not initialized, UMS-Indirect must retrieve all replicas from the DHT.

5.4 Effect of Failures
In this section, we investigate the effect of failures on the response time of UMS. In the previous tests, the value of failure
rate was 5%. In this section, we vary the value of fail rate and investigate its effect on response time.

Figure 11 shows how response time evolves when increasing the fail rate, with the other parameters set as in Table 1. An increase in fail rate decreases the performance of Chord’s lookup service, so the response time of all three algorithms increases. For the cases where the failure rate is high, e.g. more than 80%, the response time of UMS-Direct is almost the same as UMS-Indirect. The reason is that if a responsible of timestamping fails, both UMS-Direct and UMS-Indirect need to use the indirect algorithm for initializing the counters at the next responsible of timestamping, thus their response time is the same.

![Figure 11. Response time vs. failure rate](image)

Figure 11. Response time vs. failure rate

5.5 Effect of Update Frequency
In this section, we study the effect of the frequency of updates on the performance of UMS. In the previous experiments, updates on each data were timed by a Poisson process with an average rate of 1/hour. In this section, we vary the average rate (i.e. frequency of updates) and investigate its effect on response time.

Using our simulator, Figures 12 shows how response time evolves while increasing the frequency of updates with the other simulation parameters set as in Table 1. The response time decreases by increasing the frequency of updates. The reason is that an increase in the frequency of updates decreases the distance between the time of the latest update and the retrieval time, and this increases the probability of currency and availability, so the number of replicas which UMS retrieves for finding a current replica decreases.

6. RELATED WORK
In the context of distributed systems, data replication has been widely studied to improve both performance and availability. Many solutions have been proposed in the context of distributed database systems for managing replica consistency [17], in particular, using eager or lazy (multi-master) replication techniques. However, these techniques either do not scale up to large numbers of peers or raise open problems, such as replica reconciliation, to deal with the open and dynamic nature of P2P systems.

Data currency in replicated databases has also been widely studied, e.g. [1], [10], [11], [14], [22] and [26]. However, the main objective is to trade currency and consistency for performance while controlling the level of currency or consistency desired by the user. Our objective in this paper is different, i.e. return the current (most recent) replica as a result of a get request.

Most existing P2P systems support data replication, but without consistency guarantees. For instance, Gnutella [9] and KaZaA [12], two of the most popular P2P file sharing systems allow files to be replicated. However, a file update is not propagated to the other replicas. As a result, multiple inconsistent replicas under the same identifier (filename) may co-exist and it depends on the peer that a user contacts whether a current replica is accessed.

PGrid is a structured P2P system that deals with the problem of updates based on a rumor-spreading algorithm [7]. It provides a fully decentralized update scheme, which offers probabilistic guarantees rather than ensuring strict consistency. However, replicas may get inconsistent, e.g. as a result of concurrent updates, and it is up to the users to cope with the problem.

The Freenet P2P system [3] uses a heuristic strategy to route updates to replicas, but does not guarantee data consistency. In Freenet, the query answers are replicated along the path between the peers owning the data and the query originator. In the case of an update (which can only be done by the data’s owner), it is routed to the peers having a replica. However, there is no guarantee that all those peers receive the update, in particular those that are absent at update time.

Many of existing DHT applications such as CFS [4], Past [24] and OceanStore [20] exploit data replication for solving the problem of hot spots and also improving data availability. However, they generally avoid the consistency problem by restricting their focus on read-only (immutable) data.

The BRICKS project [13] deals somehow with data currency by considering the currency of replicas in the query results. For replicating a data, BRICKS stores the data in the DHT using multiple keys, which are correlated to the key $k$ by which the user wants to store the data. There is a function that, given $k$, determines its correlated keys. To deal with the currency of replicas, BRICKS uses versioning. Each replica has a version number which is increased after each update. However, because of concurrent updates, it may happen that two different replicas have the same version number thus making it impossible to decide which one is the current replica. In addition, to return a current replica, all replicas need to be retrieved in order to select the latest version. In our solution, concurrent updates raise no problem, i.e. this is a consequence of the monotonicity property of timestamps.
which are generated by KTS. In addition, our solution does not need to retrieve all replicas, and thus is much more efficient.

7. CONCLUSION
To ensure high data availability, DHTs typically rely on data replication, yet without currency guarantees for updateable data. In this paper, we proposed a complete solution to the problem of data availability and currency in replicated DHTs. Our main contributions are the following.

First, we proposed a new service called Update Management Service (UMS) which provides efficient retrieval of current replicas. For update operations, the algorithms of UMS rely on timestamping. UMS supports concurrent updates. Furthermore, it has the ability to determine whether a replica is current or not without comparing it with other replicas. Thus, unlike the solution in [13], our solution does not need to retrieve all replicas for finding a current replica, and is much more efficient.

Second, we gave a probabilistic analysis of UMS’s communication cost by computing the expected number of replicas which UMS must retrieve. We proved that this number is less than the inverse of the probability of currency and availability. Thus, except for the cases where the availability of current replicas is very low, the expected number of retrieved replicas is typically small, e.g. if at least 35% of replicas are current and available then this number is less than 3.

Third, we proposed a Key-based Timestamping Service (KTS) which generates monotonically increasing timestamps in a completely distributed fashion, using local counters. The dynamic behavior of peers causes no problem for KTS. To preserve timestamp monotonicity, we proposed a direct and an indirect algorithm. The direct algorithm deals with the situations where peers leave the system normally, i.e. without failing. The indirect algorithm takes into account the situations where peers fail. Although the indirect algorithm has high probability of success in general, there are rare situations where it may not be successful at finding the current replica. We proposed two strategies to deal with these situations.

Fourth, we validated our solution through implementation and experimentation over a 64-node cluster and evaluated its scalability through simulation over 10,000 peers using SimJava. We compared the performance of UMS and BRK (from the BRICK project) which we use as baseline algorithm. The experimental and simulation results show that using KTS, UMS achieves major performance gains, in terms of response time and communication cost, compared with BRK. The response time and communication cost of UMS grow logarithmically with the number of peers of the DHT. Increasing the number of replicas, which we replicate for each data in the DHT, increases very slightly the response time and communication cost of our algorithm. In addition, even with a high number of peer fails, UMS still works well. In summary, this demonstrates that data currency, a very important requirement for many applications, can now be efficiently supported in replicated DHTs.
